Rotational Surfaces in $\mathbb{L}^3$ and Solutions of the Nonlinear Sigma Model

Manuel Barros, Magdalena Caballero and Miguel Ortega*

Departamento de Geometría y Topología, Universidad de Granada, 18071 Granada, Spain

Abstract

The Gauss map of non-degenerate surfaces in the three-dimensional Minkowski space are viewed as dynamical fields of the two-dimensional $O(2,1)$ Nonlinear Sigma Model. In this setting, the moduli space of solutions with rotational symmetry is completely determined. Essentially, the solutions are warped products of orbits of the 1-dimensional groups of isometries and elastic curves in either a de Sitter plane, a hyperbolic plane or an anti de Sitter plane. The main tools are the equivalence of the two-dimensional $O(2,1)$ Nonlinear Sigma Model and the Willmore problem, and the description of the surfaces with rotational symmetry. A complete classification of such surfaces is obtained in this paper. Indeed, a huge new family of Lorentzian rotational surfaces with a space-like axis is presented. The description of this new class of surfaces is based on a technique of surgery and a gluing process, which is illustrated by an algorithm.

MSC 2000 Classification: Primary 53C40; Secondary 53C50
PACS: 11.10.Lm; 11.10.Ef; 11.15.-q; 11.30.-j; 02.30.-f; 02.40.-k
Keywords: $O(3)$ and $O(2,1)$ nonlinear sigma models; Elastica; Boundary value problem; solution; Willmore surfaces.

1 Introduction

Nonlinear sigma models are field theories whose elementary fields, or dynamical variables, are maps, ϕ, from a space, M, the source space, to an auxiliary space, $\mathbf{E}$, the target space, endowed with a non-degenerate metric. The Lagrangian governing the dynamics of the model measures the total energy of those maps. The classical solutions of the model, i. e., the solutions of the corresponding field equations, constitute the space of field configurations. The dimension of the source space is called the dimension of the model. The isometry group, $\mathbf{A}$, of the target space is the symmetry of the model. In particular, when M is compact and Riemannian, each solution has finite energy. In this sense, we call them solitons.

Two-dimensional nonlinear sigma models, in particular those with symmetry $O(3)$ and $O(2,1)$, are ubiquitous in Physics (see for example [13, 37] and references therein); with applications going from Condensed-matter Physics (see [7, 22, 23] and references therein) to High-energy Physics (see [1, 2, 20, 28] and references therein) and, of course, Quantum Field Theory (see [24, 33] and references therein). In particular, those with Minkowski signature metric on the target space are applied to Gauge Theories (see [1, 35]), Quantum Gravity (see [36]), String Theories (see [10, 36]), Quantum Mechanics (see [16]) and General Relativity, in particular Einstein and Ernst equations (see [14, 18]). They are specially important in string theories where the model description is applicable. This kind of universality is strongly related to the fact that these sigma models, and the equations governing their dynamics, have a deep underlying geometric meaning. This provides a powerful reason to explain the great interest of these models in Applied Mathematics and in Differential Geometry, even without mentioning any physical terminology, simply as a kind of constrained Willmore problem (see, for example, [3, 4, 9, 12] and references therein). In this framework, it seems natural to identify the dynamical variables of the two-dimensional $O(3)$ Nonlinear Sigma Model with the Gauss maps of surfaces in the three-dimensional Euclidean space. This approach has been successfully used to obtain certain moduli spaces of solutions: with constant mean curvature, [7, 17, 26, 32], those admitting a rotational symmetry, [5], and those foliated by Villarceau circles, [6].

The study of moduli spaces of solutions (field configurations) of the two-dimensional $O(2,1)$ Nonlinear Sigma Model constitutes an ambitious program. We will develop it along a series of articles, starting with this one. Beforehand, it will be useful to remark the following general points related to this model:

- The Gauss map of any nondegenerate surface in the three-dimensional Lorentz-Minkowski space, $\mathbb{L}^3$, is automatically an elementary field of this model. Therefore, the geometrical approach identifies the space of dynamical variables with that of Gauss maps of nondegenerate surfaces in $\mathbb{L}^3$.

- On the other hand, the underlying variational problem of this model turns out to be equivalent to the Willmore variational problem (see Theorem 3.2). This has important consequences:

    1. The field configurations of this model are nothing but the Willmore surfaces in $\mathbb{L}^3$.
    2. The model is invariant under conformal changes of the metric of $\mathbb{L}^3$.
    3. Since the Willmore functional is essentially the Polyakov action, the model can be regarded as a bosonic string theory in $\mathbb{L}^3$ that is governed by the Willmore-

Polyakov action. In this sense, the solutions of the model provide the string world sheet configurations (see [30, 31]).

Now, the first step in the above program, which constitutes the main aim of this paper, is stated as follows:

> **To determine the moduli space of solutions of the two-dimensional $O(2,1)$ Nonlinear Sigma Model that admit a rotational symmetry. Equivalently, classify, up to congruences, those rotational surfaces in $\mathbb{L}^3$ that are critical points of the total energy.**

This problem is much more difficult and subtle than its Riemannian partner, [5], and it will be treated according to the causal character of the symmetry axis. Indeed, in Section 4, we have studied and completely solved the case where the symmetry axis is time-like, that is, surfaces invariant under a one parameter group, $\mathbf{A}_1$, of elliptic motions. This can be summarized as follows:

1. Firstly, we consider the nonlinear sigma model with boundary and we determine the admissible boundary conditions.
2. Next, we obtain the space of surfaces that are invariant under rotations with time-like axis.
3. Then, since the orbits are circles, we use the principle of symmetric criticality, [29], and the conformal invariance of the model to make a suitable conformal change to obtain that

> **The solutions of the two-dimensional $O(2,1)$ Nonlinear Sigma Model that admit a rotational symmetry with time-like axis are obtained by rotating clamped free elastic curves (critical points of the total squared curvature) in the anti de Sitter plane**.

The major part of the paper is devoted to obtaining rotational solutions with space-like axis. This case is the most complicated.

The first important difficulty is to obtain the whole class of rotational surfaces in $\mathbb{L}^3$ with space-like axis, in other words, surfaces that are invariant under a one parameter group, $\mathbf{A}_2$, of hyperbolic motions. This problem, which has been usually avoided in the literature, perhaps because of its difficulty, is completely solved in Section 5. To understand this problem, assume that the space-like axis coincides with the $\{x\}$-axis. Then, the planes $y = z$ and $y = -z$ divide $\mathbb{L}^3$ in four open regions, which will be called fundamental regions. Certainly, for every fundamental region we can get a class of rotational surfaces, with $\{x\}$-axis, immersed in the region. These surfaces are well known in the literature (see for example [19]). However, there are rotational surfaces with $\{x\}$-axis in $\mathbb{L}^3$ that leave a fundamental region to emerge in another fundamental region. This family includes popular surfaces, such as a saddle surface and the one-sheet hyperboloid with $\{z\}$-axis. In some sense, these surfaces can be obtained by gluing two or more surfaces, each of them contained in a fundamental region. Along Section 5, we use surgery to dissect these surfaces and to understand the gluing mechanism. At the end of it, we obtain a classification theorem (see Theorem 5.14) and a construction algorithm (see Subsection 5.7).

Once we have obtained the whole space of rotational surfaces with space-like axis, there are, at least, two different ways to get the corresponding solutions. On one hand, one can try to carry out a symmetry reduction of the action principle. This procedure depends on a kind of symmetric criticality principle that should be established. However, there is a second way that consists in a direct variational approach. Therefore, one needs to obtain the field equations governing the model. Since the model turns out to be equivalent to a constricted Willmore model, in Section 6, we obtain the first variation that provides Willmore surfaces in a general semi-Riemannian background.

In Section 7, we obtain the whole moduli space of Riemannian solutions with a rotational symmetry with space-like axis(see Theorem 7.1).

> **The Riemannian solutions of the two-dimensional $O(2,1)$ Nonlinear Sigma Model that admit a rotational symmetry with space-like axis are obtained by rotating space-like clamped free elastic curves of the de Sitter plane**.

In Section 8, the whole moduli space of Lorentzian solutions with a rotational symmetry with space-like axis is obtained. Firstly, we study those solutions that are contained in a fundamental region (fundamental solutions).

> **On one hand, we get solutions coming from time-like clamped free elastic curves in the de Sitter plane** (Theorem 8.1). **On the other hand, we also obtain a second family of Lorentzian solutions, which are generated by clamped free elastic curves in the hyperbolic plane** (Theorem 8.2).

Certainly, each solution in those families is contained in a fundamental region. In contrast with the Riemannian case, we can find Lorentzian solutions in all the fundamental regions. This fact allows us to study the existence of solutions leaving a fundamental region and emerging in another one. In other words, we look for solutions obtained by gluing fundamental solutions. This problem is completely solved at the end of Section 8. In fact, such solutions are surfaces that are connected pieces of either a one-sheet hyperboloid with time-like axis and centered at any point of the space-like axis, or a Lorentzian plane orthogonal to the space-like axis (Theorem 8.3).

Finally, in the last section we consider the case where solutions admit a one parameter group, $\mathbf{A}_3$, of parabolic transformations. They are known in the literature as rotational surfaces with light-like axis, [19]. Now, parabolic rotational surfaces lie in two fundamental regions of $\mathbb{L}^3$. In contrast with the case of rotational surfaces with space-like axis, in Section 9 we prove that we can not find parabolic rotational surfaces that leave a fundamental region to emerge in the other. At the end of that section, we obtain the complete classification of $\mathbf{A}_3$-invariant solutions (see Theorem 9.2).

The solutions of the two-dimensional $O(2,1)$ Nonlinear Sigma Model that admit a rotational symmetry with light-like axis are obtained by rotating clamped free elastic curves of the anti de Sitter plane.

The results of this paper can be summarized in the following statement.

The solutions of the two-dimensional $O(2,1)$ Nonlinear Sigma Model that admit a rotational symmetry are the following surfaces:

1. **A connected piece (with boundary) of a Lorentzian plane.**
2. **A connected piece (with boundary) of a one-sheet hyperboloid with time-like axis.**
3. **A surface generated, via rotations, by a clamped free elastic curve according to the following table.**

Symmetry Group	**Axis**	**Orbits**	**Character of the surface**	**Generating Curve**
$\mathbf{A}_1$	Time-like	Circles	Riemannian	Space-like free elastic curve in the anti de Sitter plane
$\mathbf{A}_1$	Time-like	Circles	Lorentzian	Time-like free elastic curve in the anti de Sitter plane
$\mathbf{A}_2$	Space-like	Hyperbolas	Riemannian	Space-like free elastic curve in the de Sitter plane
$\mathbf{A}_2$	Space-like	Hyperbolas	Lorentzian	Time-like free elastic curve in the de Sitter plane
$\mathbf{A}_2$	Space-like	Hyperbolas	Lorentzian	Free elastic curve in the hyperbolic plane
$\mathbf{A}_3$	Light-like	Parabolas	Riemannian	Space-like free elastic curve in the anti de Sitter plane
$\mathbf{A}_3$	Light-like	Parabolas	Lorentzian	Time-like free elastic curve in the anti de Sitter plane

2 Preliminaries and Generalities

Along this paper the geometrical objects are C^∞ or equivalently smooth, though those appearing in the paper could be supposed to be only as differentiable as needed.

Let M be a surface with (or without) boundary and $\phi : M \longrightarrow \mathbb{L}^3$ an immersion in the Lorentz-Minkowski three space with flat metric $g = \langle , \rangle$. If $d\phi_p(T_pM)$ is a non-degenerate plane in $\mathbb{L}^3$ for any $p \in M$, then $\phi : (M, \phi^*(g)) \longrightarrow \mathbb{L}^3$ is said to be a non-degenerate isometric immersion (or a non degenerate surface). A non-degenerate surface can be oriented, at least locally, by a unitary normal vector field, say N_ϕ. According to the causal character, $\langle N_\phi, N_\phi \rangle = \varepsilon$, we have two possibilities:

Lorentzian surfaces (also called time-like surfaces). When $\varepsilon = 1$, N_ϕ is space-like and so $(M, \phi^*(g))$ is a Lorentzian surface. The unitary normal vector field, N_ϕ, can be viewed as a map, the Gauss map, $N_\phi : M \longrightarrow \mathbb{S}^2_1$, where $\mathbb{S}^2_1 = \{\vec{v} \in \mathbb{L}^3 : \langle \vec{v}, \vec{v} \rangle = 1\}$ is the de Sitter plane.

Riemannian surfaces (also named space-like surfaces). When $\varepsilon = -1$, N_ϕ is time-like and so $(M, \phi^*(g))$ is a Riemannian surface. In this case, the Gauss map is defined as $N_\phi : M \longrightarrow \mathbb{H}^2$, where $\mathbb{H}^2 = \{\vec{v} \in \mathbf{C}^\uparrow \subset \mathbb{L}^3 : \langle \vec{v}, \vec{v} \rangle = -1\}$ is the hyperbolic plane and $\mathbf{C}^\uparrow$ denotes the future cone.

Let us denote by $O(2,1)$ the matrix representation of the group of vectorial isometries of $\mathbb{L}^3$, $\mathrm{Iso}(\mathbb{L}^3)$, also known as the group of Lorentz transformations. Since the group of isometries of both $\mathbb{S}^2_1$ and $\mathbb{H}^2$ is $O(2,1)$, the Gauss map of non-degenerate surfaces can be regarded as elementary fields in the two-dimensional $O(2,1)$ Nonlinear Sigma Model (sometimes we will abbreviate it as $O(2,1)$ NSM). The Lagrangian density governing this field theory is precisely $\|dN_\phi\|^2$, which can be computed, via the Gauss equation, in terms of the mean curvature, H_ϕ, of (M, ϕ) and the Gaussian curvature, K_ϕ, of $(M, \phi^*(g))$, i. e.,

$$\|dN_\phi\|^2 = 4H_\phi^2 - 2\varepsilon K_\phi. \tag{1}$$

Consider $\mathrm{Iso}^{+\uparrow}(\mathbb{L}^3) = \{f \in \mathrm{Iso}(\mathbb{L}^3) : \det(f) = 1, f(\mathbf{C}^\uparrow) = \mathbf{C}^\uparrow\}$. Its partner in $O(2,1)$ is denoted by $(O(2,1))^{+\uparrow}$. It is known that each Lorentz transformation, $f \in \mathrm{Iso}(\mathbb{L}^3)$, admits at least one eigenvector with eigenvalue ± 1. Therefore, given $\vec{x} \in \mathbb{L}^3$, we wish to determine those Lorentz transformations, $f \in \mathrm{Iso}^{+\uparrow}(\mathbb{L}^3)$, such that $f(\vec{x}) = \vec{x}$. These vectorial isometries constitute a subgroup, $\mathbf{A}$, of $\mathrm{Iso}^{+\uparrow}(\mathbb{L}^3)$, called the *group of rotations with axis* $\langle \vec{x} \rangle = \mathrm{Span}\{\vec{x}\}$. Certainly, $\mathbf{A}$ acts naturally on the whole $\mathbb{L}^3$ producing orbits. However, these orbits are quite different according to the causal character of the axis. Next we summarize the corresponding discussion.

(1) Time-like axis. Choose an orthonormal basis, in $\mathbb{L}^3$, as follows $\mathcal{B} = \{\vec{x}, \vec{y}, \vec{z}\}$. We work in coordinates with respect to $\mathcal{B}$. Since the axis is time-like, then $\{\vec{y}, \vec{z}\}$ determine an Euclidean plane. In this case, the group $\mathbf{A}$ is identified with the following subgroup of $(O(2,1))^{+\uparrow}$,

$$\mathbf{A}_1 = \{1\} \times O^+(2) = \left\{ \mu_t = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos t & -\sin t \\ 0 & \sin t & \cos t \end{pmatrix} \,:\, t \in \mathbb{R} \right\}.$$

Given a point $p = (a_1, a_2, a_3) \in \mathbb{L}^3$, denote by P the Euclidean plane in $\mathbb{L}^3$ passing through p and orthogonal to $\vec{x}$. The orbit of p under the action of $\mathbf{A}_1$, $[\,p\,]_1$, is just the circle in P through p with center $(a_1, 0, 0)$, i. e., $[\,p\,]_1 = \{(a_1, y, z) \in \mathbb{L}^3 : y^2 + z^2 = a_2^2 + a_3^2\}$. Certainly, $[\,p\,]_1 = \{p\}$ if $a_2 = a_3 = 0$. Therefore, sometimes we call transformations in $\mathbf{A}_1$ elliptic motions or pure rotations.

(2) Space-like axis. Choose an orthonormal basis, in $\mathbb{L}^3$, as follows $\mathcal{B} = \{\vec{x}, \vec{y}, \vec{z}\}$. We work in coordinates with respect to this basis. Since the axis is space-like, then $\{\vec{y}, \vec{z}\}$ determine a Lorentzian plane. In this case, the group $\mathbf{A}$ is identified with the following subgroup of $O_1^{+\uparrow}(3)$,

$$\mathbf{A}_2 = \{1\} \times O_1^{+\uparrow}(2) = \left\{ \xi_t = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cosh t & \sinh t \\ 0 & \sinh t & \cosh t \end{pmatrix} \,:\, t \in \mathbb{R} \right\}. \qquad (2)$$

Given a point $p = (a_1, a_2, a_3) \in \mathbb{L}^3$, denote by P the Lorentzian plane in $\mathbb{L}^3$ passing through p and orthogonal to $\vec{x}$. It is clear that the orbit of p, $[\,p\,]_2$, is contained in P. If $a_2 = a_3 = 0$, then $[\,p\,]_2 = \{p\}$. Otherwise, we must distinguish two cases:

- If $a_2^2 = a_3^2$, then $[\,p\,]_2$ is the open half straight line starting at $(a_1, 0, 0)$ and passing through p, i. e., $[\,p\,]_2 = \{(a_1, \lambda\, a_2, \lambda\, a_3) \,:\, 0 < \lambda\}$.
- If $a_2^2 \neq a_3^2$, then $[\,p\,]_2$ is the branch of hyperbola in P centered at $(a_1, 0, 0)$ and passing through p, i. e., $[\,p\,]_2$ is the connected component of $\{(a_1, y, z) \in \mathbb{L}^3 : y^2 - z^2 = a_2^2 - a_3^2\}$ that contains p. Transformations in $\mathbf{A}_2$ will be usually called hyperbolic motions or hyperbolic rotations.

(3) Light-like axis. If $\vec{x}$ is null, then we consider a basis $\mathcal{B} = \{\vec{x}, \vec{y}, \vec{z}\}$ of $\mathbb{L}^3$ such that: (1) $\vec{y}$ is a light-like vector with $\langle \vec{x}, \vec{y} \rangle = -1$, and (2) $\vec{z}$ is a unitary space-like vector orthogonal to the plane $\operatorname{Span}\{\vec{x}, \vec{y}\}$. We work in coordinates with respect to $\mathcal{B}$. It can be checked that the group $\mathbf{A}$ is identified with the following subgroup of $O_1^{+\uparrow}(3)$,

$$\mathbf{A}_3 = \left\{ \varsigma_t = \begin{pmatrix} 1 & \frac{1}{2}t^2 & t \\ 0 & 1 & 0 \\ 0 & t & 1 \end{pmatrix} \,:\, t \in \mathbb{R} \right\}.$$

In this setting, to analyze the orbits, we must consider again a couple of cases different to that where $a_2 = a_3 = 0$, in which $[\,p\,]_3 = \{p\}$, for $p = (a_1, a_2, a_3) \in \mathbb{L}^3$.

- If $a_2 = 0$, then the orbit $[\,p\,]_3$ is a straight line, namely $[\,p\,]_3 = \{(t, 0, a_3) \,:\, t \in \mathbb{R}\}$.

- If $a_2 \neq 0$, then the orbit $[p]_3$ is a parabola in the plane $Q = \{(x, a_2, z) \in \mathbb{L}^3 : x, z \in \mathbb{R}\}$. In fact, $[p]_3 = \{(x, a_2, z) \in Q : x = \frac{1}{2a_2}(z - a_3)^2 + \frac{a_3}{a_2}(z - a_3) + a_1\}$. Thus, $\mathbf{A}_3$ will be called the group of parabolic rotations or parabolic motions.

To end this section, we define elastic curves, known also as elasticae. We consider a Riemannian or Lorentzian oriented 2-manifold (M, h), with its Levi-Civita connection ∇. We only work with Frenet curves, i. e., regular curves $\alpha : I \subset \mathbb{R} \to M$ such that the following *Frenet* equations are well-defined,

$$\nabla_T T = \epsilon_2 \kappa N, \quad \nabla_T N = -\epsilon_1 \kappa T,$$

where $\{T = \alpha'/\|\alpha'\|, N\}$ is a positive orthonormal frame along α, $\epsilon_1 = h(T, T) = \pm 1$, $\epsilon_2 = h(N, N) = \pm 1$ and κ is a smooth function, usually called the (geodesic) curvature of α. We recall that geodesics are curves such that κ vanishes identically.

Next, given two points p_1, $p_2 \in M$ and two tangent vectors $v_i \in T_{p_i}M$, $i = 1, 2$, we define a space of *clamped* curves

$$\Gamma = \{\alpha : [a_1, a_2] \to M : \alpha(a_i) = p_i,\ \alpha'(a_i) = v_i,\ i = 1, 2\}.$$

We also admit the case $p_1 = p_2$ and $v_1 = v_2$, and then, we call Γ a space of *closed* curves. Let us consider the *total squared action* on Γ,

$$\mathfrak{E} : \Gamma \to \mathbb{R}, \quad \mathfrak{E}(\alpha) = \int_\alpha (\kappa^2 + \lambda),$$

where $\lambda \in \mathbb{R}$ is a Lagrange multiplier. Thus, an *elastica* (or an elastic curve) is a critical point of $\mathfrak{E}$. In case $\lambda = 0$, we call it *free elastica*.

3 Gaussian map approach and the Conformal Invariance of the two-dimensional $O(2,1)$ NSM

The elementary fields in the two-dimensional $O(2,1)$ Nonlinear Sigma Model are $\mathbb{L}^3$-valued unitary vector fields on surfaces with (or without) boundary. Therefore, they map something of dimension two (a surface) in either a de Sitter plane, $\mathbb{S}^2_1$, or a hyperbolic one, $\mathbb{H}^2$. Along this paper, we will assume that the source space is a surface with boundary and elementary fields are subject to a natural constraint along the boundary. However, the free case, i. e., when the boundary of the surface is empty, can be regarded as a particular case with no constraints. Hence, it seems natural to approach the study of this sigma model, in connection with the differential geometry of surfaces in $\mathbb{L}^3$, by identifying the dynamical variables of the model with the Gauss map of non-degenerate surfaces in the Lorentz-Minkowski three-space. To be precise, let us state the general setting of this approach.

Let $\Gamma = \{\gamma_1, \gamma_2, \ldots, \gamma_n\}$ be a finite set of non-null regular curves in $\mathbb{L}^3$ with $\gamma_i \bigcap \gamma_j = \emptyset$, if $i \neq j$. Let N_o be a unitary vector field along Γ orthogonal to Γ and with constant causal character on the whole Γ, i. e.,

$$\begin{aligned} \langle \Gamma'(p), N_o(p) \rangle &= 0, \quad \forall p \in \Gamma, \text{ and} \\ \langle N_o(p), N_o(p) \rangle &= \varepsilon, \quad \forall p \in \Gamma, \text{ where } \varepsilon \in \{1, -1\}. \end{aligned}$$

Notice that, if $\varepsilon = 1$, Γ could consist of both time-like and space-like curves at the same time. Furthermore, Γ' and N_o determine a third vector field along Γ given by $N_o = \Gamma' \wedge \nu$.

On the other hand, let M be a connected smooth surface with boundary, $\partial M = c_1 \cup c_2 \cup \ldots \cup c_n$. We denote by $\mathbf{I}^{\varepsilon}_{\Gamma}(M, \mathbb{L}^3)$ the space of immersions, $\phi : M \longrightarrow \mathbb{L}^3$ with unitary normal vector field, N_ϕ, satisfying $\langle N_\phi, N_\phi \rangle = \varepsilon$ and the following boundary conditions:

1. $\phi(\partial M) = \Gamma$, namely $\phi(c_j) = \gamma_j$, $1 \leq j \leq n$, and
2. $d\phi_q(T_q M)$ is orthogonal to $N_o(\phi(q))$, $\forall q \in \partial M$; this is equivalent to say $N_\phi|_{\Gamma} = N_o$.

Roughly speaking, if we identify each immersion $\phi \in \mathbf{I}^{\varepsilon}_{\Gamma}(M, \mathbb{L}^3)$ with its graph, $\phi(M)$, viewed as a surface with boundary in $\mathbb{L}^3$, then $\mathbf{I}^{\varepsilon}_{\Gamma}(M, \mathbb{L}^3)$ can be regarded as the space of immersed surfaces in $\mathbb{L}^3$ having the same causal character, the same boundary and the same Gauss map along the common boundary.

In this setting, the action governing the two-dimensional $O(2,1)$ Nonlinear Sigma Model, $\mathfrak{S} : \mathbf{I}^{\varepsilon}_{\Gamma}(M, \mathbb{L}^3) \longrightarrow \mathbb{R}$, can be written as

$$\mathfrak{S}(\phi) = \int_M \|dN_\phi\|^2 \, dA_\phi, \tag{3}$$

where dA_ϕ denotes the element of area of $(M, \phi^*(g))$. The solutions of the two-dimensional $O(2,1)$ Nonlinear Sigma Model are just the critical points of $(\mathbf{I}^{\varepsilon}_{\Gamma}(M, \mathbb{L}^3), \mathfrak{S})$.

Next, we define a *non-null polygon* as a connected, simply-connected, compact domain $\mathsf{K} \subset M$ with nonempty interior and with piecewise smooth boundary, $\partial \mathsf{K}$, made up of a finite number of smooth non-null curves. The concept of solution can be materialized according to the following

Definition 3.1 *$\phi \in \mathbf{I}^{\varepsilon}_{\Gamma}(M, \mathbb{L}^3)$ is a critical point of $(\mathbf{I}^{\varepsilon}_{\Gamma}(M, \mathbb{L}^3); \mathfrak{S})$ if for any non-null polygon $\mathsf{K} \subseteq M$, the restriction $\phi|_{\mathsf{K}}$ is a critical point of $\left(\mathbf{I}^{\varepsilon}_{\phi(\partial\mathsf{K})}(\mathsf{K}, \mathbb{L}^3); \mathfrak{S}^{\mathsf{K}}\right)$, where*

- *$\mathbf{I}^{\varepsilon}_{\phi(\partial\mathsf{K})}(\mathsf{K}, \mathbb{L}^3)$ is the space of immersions, $\psi : \mathsf{K} \longrightarrow \mathbb{L}^3$, which satisfy $\psi|_{\partial\mathsf{K}} = \phi|_{\partial\mathsf{K}}$; $N_\psi|_{\partial\mathsf{K}} = N_\phi|_{\partial\mathsf{K}}$ and $\langle N_\psi, N_\psi \rangle = \varepsilon$, and*
- *$\mathfrak{S}^{\mathsf{K}}(\psi) = \int_{\mathsf{K}} \|dN_\psi\|^2 \, dA_\psi$, where dA_ψ denotes the element of area of $(\mathsf{K}, \psi^*(g))$.*

Once we have shown the Gaussian map approach to the $O(2,1)$ Nonlinear Sigma Model, we focus on proving its conformal invariance.

The Willmore functional for free boundary surfaces in the Euclidean space, [40], was extended to surfaces with boundary, [39]. This functional can also be considered for non-degenerate surfaces in the Lorentz-Minkowski space and so extended to those with non-null boundary. In particular, we can define $\mathfrak{W} : \mathbf{I}^{\varepsilon}_{\Gamma}(M, \mathbb{L}^3) \longrightarrow \mathbb{R}$ as

$$\mathfrak{W}(\phi) = \int_M H_\phi^2 \, dA_\phi + \int_{\partial M} \kappa_\phi \, ds, \tag{4}$$

where κ_ϕ is the geodesic curvature of ∂M in $(M, \phi^*(g))$. This action defines a variational problem which is invariant under conformal transformations in $\mathbb{L}^3$. The corresponding critical points, which can be defined similarly to those of the action $\mathfrak{S}$, are called *Willmore surfaces* (or Willmore surfaces with prescribed Gauss map along the boundary). The following result provides a strong relationship between the variational problems associated with both functionals

Theorem 3.2 *The two-dimensional $O(2,1)$ Nonlinear Sigma Model, $(\mathbf{I}^{\varepsilon}_{\Gamma}(M, \mathbb{L}^3); \mathfrak{S})$, turns out to be equivalent to the Willmore variational problem $(\mathbf{I}^{\varepsilon}_{\Gamma}(M, \mathbb{L}^3); \mathfrak{W})$. In particular,*

1. *Both have the same critical points. That is, $\phi \in \mathbf{I}^{\varepsilon}_{\Gamma}(M, \mathbb{L}^3)$ is a solution of the two-dimensional $O(2,1)$ Nonlinear Sigma Model if and only if (M, ϕ) is a Willmore surface.*

2. *The two-dimensional $O(2,1)$ Nonlinear Sigma Model is invariant under conformal changes in the metric of $\mathbb{L}^3$.*

Proof: If $\varepsilon = -1$, then the immersions $\phi \in \mathbf{I}^{-1}_{\Gamma}(M, \mathbb{L}^3)$, provide Riemannian surfaces, $\phi(M)$, in $\mathbb{L}^3$. Consequently, we can follow, up to slight changes, the proof made in [5] for surfaces in the Euclidean space.

If $\varepsilon = 1$, choose an immersion $\phi \in \mathbf{I}^{1}_{\Gamma}(M, \mathbb{L}^3)$. Then, it provides a Lorentzian surface, $\phi(M)$, in $\mathbb{L}^3$. Given K any non-null polygon, the main aim is to relate the actions $\mathfrak{S}^{\mathsf{K}}, \mathfrak{M}^{\mathsf{K}} : \mathbf{I}^{-1}_{\phi(\partial \mathsf{K})}(\mathsf{K}, \mathbb{L}^3) \longrightarrow \mathbb{R}$. Therefore, the first step is to use the formula (1) and next to get control on the total Gaussian curvature. To do so, we need a Gauss-Bonnet formula working on non-null polygons, no matter the causal character of the boundary pieces. This is made, with details, in the Appendix. So, after applying this formula, we get

$$\mathfrak{S}^{\mathsf{K}}(\psi) = 4\,\mathfrak{M}^{\mathsf{K}}(\psi) - 6 \int_{\partial \mathsf{K}} \kappa_\psi \, ds - 2 \sum_{j=1}^{r} \theta_j .$$

Finally, the nature of the hyperbolic angle joint the formula (15), (see Appendix), are used to show that the action measuring the total geodesic curvature of $\psi(\partial \mathsf{K}) = \phi(\partial \mathsf{K})$ indeed does not depend on $\psi \in \mathbf{I}^{-1}_{\phi(\partial \mathsf{K})}(\mathsf{K}, \mathbb{L}^3)$. This concludes the proof of the result. □

4 Solutions of the $O(2,1)$ NSM which are $\mathbf{A}_1$-invariant

In this section, we completely determine the moduli space of solutions of the two-dimensional $O(2,1)$ Nonlinear Sigma Model, $(\mathbf{I}^{\varepsilon}_{\Gamma}(M,\mathbb{L}^3);\mathfrak{S})$, which, in addition, are invariant under $\mathbf{A}_1$, i. e., the group of rotations with time-like axis, $\langle\vec{x}\rangle$.

Firstly, we need to establish this previous problem in a suitable way. In fact, the boundary conditions, (Γ, N_o), cannot be arbitrary but invariant under the $\mathbf{A}_1$-action. This invariance holds if and only if the following conditions are satisfied:

1. The boundary, Γ, consists of a pair of circles, $\{\gamma_1,\gamma_2\}$, contained in Euclidean planes, P_1, P_2, which are orthogonal to the time-like axis, $\langle\vec{x}\rangle$, and centered at the points $P_i \bigcap \langle\vec{x}\rangle$, $i=1,2$.
2. The unitary normal vector field, N_o, along $\Gamma=\{\gamma_1,\gamma_2\}$, satisfies $\langle N_o,\vec{x}\rangle = \text{constant}$.

Consequently, the topology of the surface is $M=[\,a_1,a_2]\times\mathbb{S}^1$.

Secondly, the action of $\mathbf{A}_1$ on $\mathbb{L}^3$ can be naturally extended to $\mathbf{I}^{\varepsilon}_{\Gamma}(M,\mathbb{L}^3)$ as follows

$$\mathbf{A}_1\times\mathbf{I}^{\varepsilon}_{\Gamma}(M,\mathbb{L}^3)\longrightarrow\mathbf{I}^{\varepsilon}_{\Gamma}(M,\mathbb{L}^3),\quad (\mu_t,\phi)\mapsto\mu_t\circ\phi.$$

It is obvious that both functionals, $\mathfrak{S}$ and $\mathfrak{W}$ are invariant under this action, i. e.,

$$\mathfrak{S}(\mu_t\circ\phi)=\mathfrak{S}(\phi),\ \mathfrak{W}(\mu_t\circ\phi)=\mathfrak{W}(\phi),\quad \forall t\in\mathbb{R} \text{ and } \phi\in\mathbf{I}^{\varepsilon}_{\Gamma}(M,\mathbb{L}^3).$$

Define the set of the immersions which are invariant under $\mathbf{A}_1$, also called symmetric points, as $\Sigma^{\varepsilon}=\{\phi\in\mathbf{I}^{\varepsilon}_{\Gamma}(M,\mathbb{L}^3)\,:\,\mu_t\circ\phi=\phi,\,\forall t\in\mathbb{R}\}$. To identify Σ^{ε}, choose an orthonormal basis, $\mathcal{B}=\{\vec{x},\vec{y},\vec{z}\}$, in $\mathbb{L}^3$ and take the Lorentzian half-plane $\mathbf{AdS_2}=\{\vec{v}\in\mathbb{L}^3\,:\,\langle\vec{v},\vec{y}\rangle>0,\,\langle\vec{v},\vec{z}\rangle=0\}$. Let $\mathbf{C}^{\varepsilon}$ be the space of curves, $\alpha:[s_1,s_2]\longrightarrow\mathbf{AdS}_2$, satisfying the following conditions, up to a reparametrization:

- $\langle\alpha'(s),\alpha'(s)\rangle=-\varepsilon$,
- $\alpha(s_i)=\text{trace}(\gamma_i)\cap\mathbf{AdS}_2$, $i=1,2$, and
- $\alpha'(s_i)=\nu(\alpha(s_i))$, $i=1,2$.

Since $M=[\,a_1,a_2]\times\mathbb{S}^1$, for each $\alpha\in\mathbf{C}^{\varepsilon}$, we can construct the immersion $\phi_\alpha\in\mathbf{I}^{\varepsilon}_{\Gamma}(M,\mathbb{L}^3)$ defined as $\phi_\alpha(s,e^{it})=\mu_t(\alpha(s))$. It is obvious that $\phi_\alpha\in\Sigma^{\varepsilon}$. The converse also holds. Indeed, given $\phi\in\Sigma^{\varepsilon}$, we can find $\alpha\in\mathbf{C}^{\varepsilon}$ such that $\phi=\phi_\alpha$. As a consequence, we can identify Σ^{ε} with $\mathbf{C}^{\varepsilon}$. On the other hand, since $\mathbf{A}_1$ is compact, we can apply the principle of symmetric criticality [29]. According to this principle, the critical points of $\mathfrak{W}$ (equivalently $\mathfrak{S}$) which are symmetric are just the critical points of $\mathfrak{W}$ (equivalently $\mathfrak{S}$) when restricted to Σ^{ε}.

The following result provides, up to similarities in $\mathbb{L}^3$, all the solutions of the two-dimensional $O(2,1)$ Nonlinear Sigma Model which are invariant under $\mathbf{A}_1$.

Theorem 4.1 *An immersion* $\phi_\alpha \in \mathbf{I}^\varepsilon_\Gamma(M, \mathbb{L}^3)$ *is a solution of the two-dimensional* $O(2,1)$ *Nonlinear Sigma Model if and only if the curve* α *is a free elastica of* $\mathbf{AdS}_2$ *when viewed as an anti de Sitter plane.*

Proof: First, we view a piece of the Lorentz-Minkowski three space as a warped product:

$$\left(\mathbb{L}^3 \setminus \langle \vec{x} \rangle, g\right) = (\mathbf{AdS}_2, g) \times_h (\mathbb{S}^1, dt^2),$$

where the warping function, $h : \mathbf{AdS}_2 \longrightarrow \mathbb{R}^+$, is defined as $h(p) = \langle \vec{p}, \vec{y} \rangle$, where $\vec{p}$ denotes the position vector of the point p, and the metric in $\mathbf{AdS}_2$ is the induced from the usual one in $\mathbb{L}^3$. Next, we make an obvious conformal change to obtain a semi-Riemannian product:

$$\left(\mathbb{L}^3 \setminus \langle \vec{x} \rangle, \bar{g} = \frac{1}{h^2}\, g\right) = (\mathbf{AdS}_2, \bar{g}) \times (\mathbb{S}^1, dt^2).$$

An easy computation shows that $(\mathbf{AdS}_2, \bar{g})$ has constant Gaussian curvature -1, which proves that it is an anti de Sitter plane. Denote by $\mathfrak{W}$ and $\overline{\mathfrak{W}}$ the Willmore functionals of g and $\bar{g}$, respectively. We compute their restriction to Σ^ε as follows

$$\mathfrak{W}(\phi_\alpha) = \overline{\mathfrak{W}}(\phi_\alpha) = \int_M \left(\overline{H}^2_\alpha + \overline{R}_\alpha\right) d\overline{A}_\alpha + \int_{\partial M} \overline{\kappa}\, ds,$$

where $\overline{R}_\alpha$ stands for the sectional curvature of $(\mathbb{L}^3 \setminus \langle \vec{x} \rangle, \bar{g})$ along $d\phi(TM)$. Notice that in this case $\overline{R}_\alpha = 0$ because $d\phi(TM)$ is a mixed section in a semi-Riemannian product (see [27]). Furthermore, the geodesic curvature of ∂M in $(M, \phi^*_\alpha(\bar{g}))$, $\overline{\kappa}$, also vanishes identically since $\Gamma = \phi(\partial M)$ is made up of two geodesics in $(\phi(M), \bar{g})$. Next, we compute the mean curvature function of $\phi(M)$ in $(\mathbb{L}^3 \setminus \langle \vec{x} \rangle, \bar{g})$, obtaining

$$\overline{H}^2_\alpha = \frac{1}{4}\overline{\kappa}^2_\alpha,$$

where $\overline{\kappa}_\alpha$ denotes the curvature function of α in the anti de Sitter plane $(\mathbf{AdS}_2, \bar{g})$. As a consequence, we have

$$\mathfrak{W}(\phi_\alpha) = \overline{\mathfrak{W}}(\phi_\alpha) = \frac{1}{4} \int_{[s_1,s_2]\times\mathbb{S}^1} \overline{\kappa}^2_\alpha\, ds\, dt = \frac{\pi}{2} \int_{[s_1,s_2]} \overline{\kappa}^2_\alpha\, ds.$$

This concludes the proof. □

The above result reduces the search of solutions with a pure rotational symmetry to curves in the anti de Sitter plane, $(\mathbf{AdS}_2, \bar{g})$, which are critical points of the following variational problem, known as the Bernouilli elastica in its Lorentzian version. The source space is the space of *clamped* curves, $\mathbf{C}^\varepsilon$, and the Lagrangian is $\mathfrak{E} : \mathbf{C}^\varepsilon \longrightarrow \mathbb{R}$, defined by

$$\mathfrak{E}(\alpha) = \int_\alpha \overline{\kappa}^2_\alpha\, ds.$$

The first variation, $\delta\mathfrak{E}(\alpha) : \mathsf{T}_\alpha\mathbf{C}^\varepsilon \longrightarrow \mathbb{R}$, associated with this functional can be computed, using a standard method which involves some integration by parts (see for example [21] for details) to be,

$$\delta\mathfrak{E}(\alpha)[W] = \int_\alpha \bar{g}(\Omega(\alpha), W)\, ds + [\mathrm{B}(\alpha, W)]_{s_1}^{s_2},$$

where Ω and B denote, respectively, the Euler-Lagrange and the boundary operators, given by

$$\begin{aligned} \Omega(\alpha) &= 2\varepsilon_2\overline{\nabla}_T^3 T + 3\varepsilon_1\overline{\nabla}_T\left(\bar{\kappa}_\alpha^2\, T\right) + 2\overline{\nabla}_T T, \\ \mathrm{B}(\alpha, W) &= 2\varepsilon_2\bar{g}(\overline{\nabla}_T W, \overline{\nabla}_T T) - \bar{g}\left(W, 2\varepsilon_2\overline{\nabla}_T^2 T + 3\varepsilon_1\bar{\kappa}_\alpha^2\, T\right), \end{aligned}$$

where $\overline{\nabla}$ is the Levi-Civita connection of $(\mathbf{AdS}_2, \bar{g})$, ε_1 is the causal character of $T = \alpha'$ and ε_2 that of the normal. By using the boundary conditions of curves in $\mathbf{C}^\varepsilon$ (clamped curves) we can see that $[\mathrm{B}(\alpha, W)]_{s_1}^{s_2} = 0$. Therefore, the elasticae of $(\mathbf{AdS}_2, \bar{g})$ are those curves in $\mathbf{C}^\varepsilon$ satisfying the Euler-Lagrange equation $\Omega(\alpha) = 0$. This equation can be transformed using the Frenet equations to obtain the following elastica equation

$$2\bar{\kappa}_\alpha'' - \bar{\kappa}_\alpha^3 + 2\varepsilon_2\,\bar{\kappa}_\alpha = 0. \tag{5}$$

Certainly $\bar{\kappa}_\alpha = 0$ is a trivial solution of this equation, which means that geodesics of $(\mathbf{AdS}_2, \bar{g})$ are elasticae. Writting $u = \bar{\kappa}_\alpha$, the above elastica equation turns out to be $2u'' - u^3 + 2\varepsilon_2\, u = 0$, which can be integrated by means of Jacobi elliptic functions, [15], to have

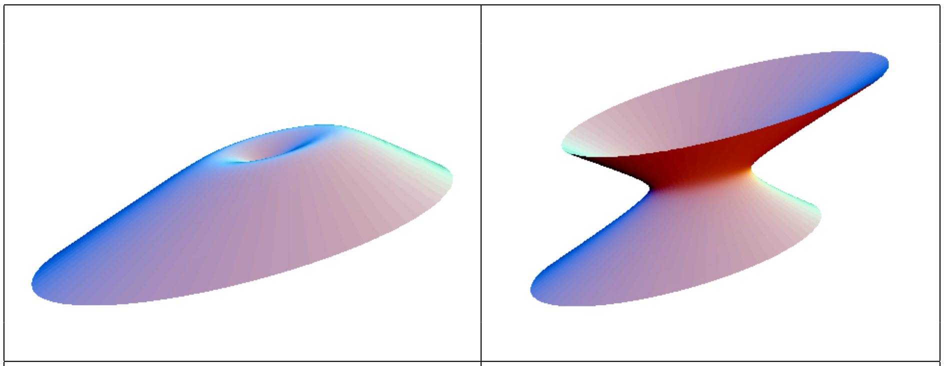
$$u(s) = C\,\mathbf{cn}\left(\lambda(s - a_o), \tilde{C}\right)$$

where $\lambda \in \mathbb{C} \setminus \{0\}$ and $a_o \in \mathbb{R}$ are arbitrary constants, $C^2 = -2\left(\lambda^2 - \varepsilon_2\right)$ and $\tilde{C}^2 = \frac{\lambda^2 - \varepsilon_2}{2\lambda^2}$. However, the elliptic cosinus of Jacobi is a complex-valued function, and the curvature must be a real-valued function. The real-valued solutions of the equation can be obtained using the properties of the Jacobi elliptic cosinus, see [11]. They provide the following curvature functions

$$\bar{\kappa}_\alpha(s) = C\,\mathbf{cn}\left(\sqrt{\varepsilon_2 - \frac{C^2}{2}}\,(s - a_o), \tilde{C}\right),$$

$$\text{for } s \in \left\{ \begin{array}{ll} \mathbb{R} \setminus \displaystyle\bigcup_{n\in\mathbb{Z}} \left\{ a_o + \frac{2n+1}{\sqrt{\frac{C^2}{2} - \varepsilon_2}}\mathsf{E}' \right\} & \text{if} \quad \varepsilon_2 - \frac{C^2}{2} < 0 \\ \mathbb{R} & \text{if} \quad \varepsilon_2 - \frac{C^2}{2} > 0 \end{array} \right\},$$

where $C \in \mathbb{R} \setminus \{-\sqrt{2\,\varepsilon_2}, \sqrt{2\,\varepsilon_2}\}$ and $a_o \in \mathbb{R}$ are arbitrary constants, $\tilde{C}^2 = \frac{C^2}{2C^2 - 4\varepsilon_2}$ and E' is the complete elliptic integral of first kind with modulus $\sqrt{1 - \tilde{C}^2}$.



$\mathbf{A}_1$-invariant Riemannian soliton | $\mathbf{A}_1$-invariant Lorentzian soliton

5 $\mathbf{A}_2$-invariant surfaces in $\mathbb{L}^3$

Next, our aim is to obtain, up to isometries of the Lorentz-Minkowski space, the whole class of solutions of the $O^1(3)$ Nonlinear Sigma Model, which are invariant under the group $\mathbf{A}_2$. A priori, it could be similar to the above studied case, but it becomes more difficult and subtle. The main difficulty we have now, is to find the symmetric points, i.e. the immersions that are invariant under $\mathbf{A}_2$.

Let denote by $\langle \vec{x} \rangle$ the space-like axis and consider the only two degenerate planes containing $\langle \vec{x} \rangle$. $\mathbb{L}^3$ minus these two planes consists of four open regions that we will call *fundamental regions*. The $\mathbf{A}_2$-invariant surfaces contained in a fundamental region will be named *fundamental symmetric surfaces*.

Certainly, we can get a wide class of surfaces invariant under $\mathbf{A}_2$ by taking a curve immersed in any non-degenerate plane of $\mathbb{L}^3$ containing $\langle \vec{x} \rangle$, whose trace does not intersect the axis, and rotating it by applying the elements of $\mathbf{A}_2$. These surfaces are those known in the literature as *rotational surfaces with space-like axis*, see for example [19]. All of them are fundamental symmetric surfaces. However, we can also find symmetric surfaces that leave a fundamental region to emerge in another one. In some sense, they are obtained by gluing fundamental symmetric surfaces. These extended surfaces have been usually avoided in the literature because of their difficulty. Nevertheless, the class includes famous surfaces, such as a saddle surface and a one-sheet hyperboloid.

In this big section, we will make an exhaustive analysis to completely describe the whole class of surfaces in $\mathbb{L}^3$ that admit a rotational group of symmetries with space-like axis, i.e. surfaces that are invariant under a group of hyperbolic rotations. For the sake of clearness, we will split our study in several subsections.

5.1 Fundamental regions and fundamental surfaces

Let $\vec{x}$ be a unitary space-like vector in $\mathbb{L}^3$. We choose an orthonormal basis, $\mathcal{B} = \{\vec{x}, \vec{y}, \vec{z}\}$, where $\vec{y}$ is also space-like and $\vec{z}$ is time-like. We work in coordinates with respect to $\mathcal{B}$, so that the metric in $\mathbb{L}^3$ is written as $g \equiv dx^2 + dy^2 - dz^2$. In $\mathbb{L}^3 \setminus \langle \vec{x} \rangle$ we will distinguish the following regions that will be called *fundamental regions*

$$\begin{aligned}
\mathcal{R}^+ &= \{(x,y,z)\in\mathbb{L}^3 \,:\, z^2-y^2>0,\, z>0\},\\
\mathcal{R}^- &= \{(x,y,z)\in\mathbb{L}^3 \,:\, z^2-y^2>0,\, z<0\},\\
\mathcal{Q}^+ &= \{(x,y,z)\in\mathbb{L}^3 \,:\, z^2-y^2<0,\, y>0\}, \text{ and}\\
\mathcal{Q}^- &= \{(x,y,z)\in\mathbb{L}^3 \,:\, z^2-y^2<0,\, y<0\}.
\end{aligned}$$

Definition 5.1 *An $\mathbf{A}_2$-invariant surface immersed in $\mathbb{L}^3$ is said to be a* fundamental symmetric surface *(or simply a fundamental surface) if it is contained in only one fundamental region.*

We define $\mathcal{R}=\{(x,y,z)\in\mathbb{L}^3 \,:\, y=0\}$ and $\mathcal{Q}=\{(x,y,z)\in\mathbb{L}^3 \,:\, z=0\}$. In this setting, we can introduce the notion of rotational surface generated by a curve.

Definition 5.2 *Let γ be a curve immersed in either $\mathcal{R}$ or $\mathcal{Q}$, with domain $\mathrm{I}\subseteq\mathbb{R}$. We define the* rotational surface generated by γ *as*

$$\mathbf{\Sigma}_\gamma := \{\xi_t(\gamma(s)) \,:\, s\in\mathrm{I},\, t\in\mathbb{R}\}.$$

Remark 5.3 *Notice that, in the case γ intersects $\langle\vec{x}\rangle$, $\mathbf{\Sigma}_\gamma$ is not a topological surface.*

Next, we consider the following open half planes

$$\begin{aligned}
\tilde{\mathcal{R}}^+ &= \mathcal{R}^+\cap\mathcal{R} = \{(x,0,z)\in\mathbb{L}^3 \,:\, z>0\},\\
\tilde{\mathcal{R}}^- &= \mathcal{R}^-\cap\mathcal{R} = \{(x,0,z)\in\mathbb{L}^3 \,:\, z<0\},\\
\tilde{\mathcal{Q}}^+ &= \mathcal{Q}^+\cap\mathcal{Q} = \{(x,y,0)\in\mathbb{L}^3 \,:\, y>0\},\\
\tilde{\mathcal{Q}}^- &= \mathcal{Q}^-\cap\mathcal{Q} = \{(x,y,0)\in\mathbb{L}^3 \,:\, y<0\},\\
\mathcal{P}^+_+ &= \big(\partial\mathcal{R}^+\cap\partial\mathcal{Q}^+\big)\setminus\langle\vec{x}\rangle = \{(x,y,z)\in\mathbb{L}^3 \,:\, y=z>0\},\\
\mathcal{P}^-_+ &= \big(\partial\mathcal{R}^+\cap\partial\mathcal{Q}^-\big)\setminus\langle\vec{x}\rangle = \{(x,y,z)\in\mathbb{L}^3 \,:\, -y=z>0\},\\
\mathcal{P}^+_- &= \big(\partial\mathcal{R}^-\cap\partial\mathcal{Q}^+\big)\setminus\langle\vec{x}\rangle = \{(x,y,z)\in\mathbb{L}^3 \,:\, y=-z>0\}, \text{ and}\\
\mathcal{P}^-_- &= \big(\partial\mathcal{R}^-\cap\partial\mathcal{Q}^-\big)\setminus\langle\vec{x}\rangle = \{(x,y,z)\in\mathbb{L}^3 \,:\, y=z<0\}.
\end{aligned}$$

We also consider the following Lorentzian unitary circles

$$\begin{aligned}
\mathcal{H}^+ &= \{(0,y,z)\in\mathbb{L}^3 \,:\, z^2-y^2=1,\, z>0\},\\
\mathcal{H}^- &= \{(0,y,z)\in\mathbb{L}^3 \,:\, z^2-y^2=1,\, z<0\},\\
\mathcal{J}^+ &= \{(0,y,z)\in\mathbb{L}^3 \,:\, y^2-z^2=1,\, y>0\}, \text{ and}\\
\mathcal{J}^- &= \{(0,y,z)\in\mathbb{L}^3 \,:\, y^2-z^2=1,\, y<0\}.
\end{aligned}$$

It should be noticed that while $\mathcal{H}^+$ and $\mathcal{H}^-$ are space-like in $\mathbb{L}^3$, with metric dt^2, $\mathcal{J}^+$ and $\mathcal{J}^-$ are time-like, with metric denoted by $-dt^2$. Next, we define the following positive functions

$$\begin{aligned}
f_+ : \tilde{\mathcal{R}}^+ \longrightarrow \mathbb{R}, \quad f_+(x,0,z) &= z,\\
f_- : \tilde{\mathcal{R}}^- \longrightarrow \mathbb{R}, \quad f_-(x,0,z) &= -z,\\
h_+ : \tilde{\mathcal{Q}}^+ \longrightarrow \mathbb{R}, \quad h_+(x,y,0) &= y, \text{ and}\\
h_- : \tilde{\mathcal{Q}}^- \longrightarrow \mathbb{R}, \quad h_-(x,y,0) &= -y.
\end{aligned}$$

In this setting, it is not difficult to check the following warped product decompositions

$$\begin{aligned}
(\mathcal{R}^+, g) &= (\tilde{\mathcal{R}}^+, g) \times_{f_+} (\mathcal{H}^+, dt^2), \\
(\mathcal{R}^-, g) &= (\tilde{\mathcal{R}}^-, g) \times_{f_-} (\mathcal{H}^-, dt^2), \\
(\mathcal{Q}^+, g) &= (\tilde{\mathcal{Q}}^+, g) \times_{h_+} (\mathcal{J}^+, -dt^2), \text{ and} \\
(\mathcal{Q}^-, g) &= (\tilde{\mathcal{Q}}^-, g) \times_{h_-} (\mathcal{J}^-, -dt^2).
\end{aligned}$$

Furthermore, when we make the obvious conformal changes, it is easy to see that:

- $\left(\tilde{\mathcal{R}}^+, \frac{1}{f_+^2} g\right)$ and $\left(\tilde{\mathcal{R}}^-, \frac{1}{f_-^2} g\right)$ are de Sitter planes with curvature 1, and
- $\left(\tilde{\mathcal{Q}}^+, \frac{1}{h_+^2} g\right)$ and $\left(\tilde{\mathcal{Q}}^-, \frac{1}{h_-^2} g\right)$ are hyperbolic planes with curvature -1.

Consequently, we obtain the following result.

Lemma 5.1 *1. $\left(\mathcal{R}^+, \frac{1}{f_+^2} g\right)$ and $\left(\mathcal{R}^-, \frac{1}{f_-^2} g\right)$ are the semi-Riemannian product of a de Sitter plane and a space-like Lorentzian unitary circle.*

2. $\left(\mathcal{Q}^+, \frac{1}{h_+^2} g\right)$ and $\left(\mathcal{Q}^-, \frac{1}{h_-^2} g\right)$ are the semi-Riemannian product of a hyperbolic plane and a time-like Lorentzian unitary circle.

5.2 Fundamental symmetric immersions

In this subsection, we completely describe those non-degenerate immersions, $\phi : M \longrightarrow \mathbb{L}^3$, whose image is a fundamental symmetric surface. We will see that they correspond with rotational surfaces generated by non-degenerate curves that do not intersect $\langle \vec{x} \rangle$. To proceed with, we consider separately Riemannian and Lorentzian cases.

Since $\mathbf{A}_2$-invariant Riemannian surfaces automatically lie in $\mathcal{R}^+$ or $\mathcal{R}^-$, the following result assures us that all the $\mathbf{A}_2$-invariant Riemannian surfaces are fundamental symmetric surfaces, and it classifies them.

Theorem 5.4 *Let M be a connected surface and $\phi : M \longrightarrow \mathbb{L}^3$ an immersion. Then, $(M, \phi^*(g))$ is Riemannian and $\mathbf{A}_2$-invariant if and only if there exists a smooth time-like curve, α, contained in either $\tilde{\mathcal{R}}^+$ or $\tilde{\mathcal{R}}^-$, such that $\phi(M) = \Sigma_\alpha$. In particular, these surfaces lie in $\mathcal{R}^+$ or $\mathcal{R}^-$.*

Proof: The sufficient condition is widely known, [19]. To prove the converse, assume that $\phi : M \longrightarrow \mathbb{L}^3$ is an immersion such that $(M, \phi^*(g))$ is Riemannian and $\phi(M)$ is invariant under the action of $\mathbf{A}_2$. This implies that $\phi(M)$ is foliated by space-like orbits. On the other hand, the orbits in $\mathcal{Q}^+ \bigcup \mathcal{Q}^-$ are time-like and those in $\mathcal{P}_+^+ \bigcup \mathcal{P}_+^- \bigcup \mathcal{P}_-^+ \bigcup \mathcal{P}_-^-$ are light-like. This shows that $\phi(M) \subset \mathcal{R}^+ \bigcup \mathcal{R}^- \bigcup \langle \vec{x} \rangle$. Consequently, there exists a space-like curve, $\alpha : J \subset \mathbb{R} \longrightarrow \mathcal{R}$, such that $\phi(M) = \{\xi_t(\alpha(s)) \, : \, s \in J, \, t \in \mathbb{R}\}$. However, if $\alpha(J) \bigcap \tilde{\mathcal{R}}^+ \neq \emptyset$

then $\alpha(J) \subset \tilde{\mathfrak{R}}^+$. Indeed, given a point $s_0 \in J$ such that $\alpha(s_0) \in \langle \vec{x} \rangle$, then the surface Σ_α is not even a topological manifold at $\alpha(s_0)$. This concludes the proof. □

In the Lorentzian case, the behavior is different. The reason is that it is possible to find $\mathbf{A}_2$-invariant Lorentzian surfaces in the four fundamental regions, according to the following result.

Theorem 5.5 *Let M be a connected surface and $\phi : M \longrightarrow \mathbb{L}^3$. Then, $(M, \phi^*(g))$ is a Lorentzian symmetric fundamental surface if and only if either*

- *there exists a time-like curve, $\alpha : \mathrm{I} \longrightarrow \tilde{\mathfrak{R}}^+$, such that $\phi(M) = \Sigma_\alpha$,*
- *there exists a time-like curve, $\alpha : \mathrm{I} \longrightarrow \tilde{\mathfrak{R}}^-$, such that $\phi(M) = \Sigma_\alpha$,*
- *there exists a space-like curve, $\alpha : \mathrm{I} \longrightarrow \tilde{\mathfrak{Q}}^+$, such that $\phi(M) = \Sigma_\alpha$, or*
- *there exists a space-like curve, $\alpha : \mathrm{I} \longrightarrow \tilde{\mathfrak{Q}}^-$, such that $\phi(M) = \Sigma_\alpha$.*

The proof is left to the reader because it is similar to the one of Theorem 5.4.

5.3 Some examples to motivate the extended Lorentzian case

For a better understanding of the general (or extended) Lorentzian case, we analyze two examples of $\mathbf{A}_2$-invariant Lorentzian surfaces that intersect more than one fundamental region.

Example 1 : A saddle surface. We consider the following saddle surface in $\mathbb{L}^3$

$$\mathbf{S} = \left\{ (x, y, z) \in \mathbb{L}^3 \,:\, x = y^2 - z^2 > -\frac{1}{4} \right\},$$

which admits a natural Monge parametrization as a graph. Indeed, in the plane $x = 0$, we consider the map

$$\mathrm{X} : \mathbb{R} \times \left(-\frac{1}{2}, \frac{1}{2} \right) \longrightarrow \mathbf{S} \subset \mathbb{L}^3, \quad \mathrm{X}(y, z) = (y^2 - z^2, y, z).$$

$\mathbf{S}$ is a Lorentzian surface in $\mathbb{L}^3$, because we have considered only the piece where the induced metric is Lorentzian. $\mathbf{S}$ is also invariant under the group $\mathbf{A}_2$. In addition, every fundamental region contains a piece of this saddle surface. According to the notation we are using, these pieces can be described as follows:

$$\begin{array}{lll} \Sigma_{\alpha^+}, & \text{where} & \alpha^+ : (0, 1/2) \to \tilde{\mathfrak{R}}^+, \ \alpha^+(s) = (-s^2, 0, s), \\ \Sigma_{\alpha^-}, & \text{where} & \alpha^- : (-1/2, 0) \to \tilde{\mathfrak{R}}^-, \ \alpha^-(s) = (-s^2, 0, s), \\ \Sigma_{\beta^+}, & \text{where} & \beta^+ : (0, +\infty) \to \tilde{\mathfrak{Q}}^+, \ \beta^+(s) = (s^2, s, 0), \ \text{and} \\ \Sigma_{\beta^-}, & \text{where} & \beta^- : (-\infty, 0) \to \tilde{\mathfrak{Q}}^-, \ \beta^-(s) = (s^2, s, 0). \end{array}$$

Obviously, these surfaces are glued along the common boundaries, obtaining **S**. Though the gluing mechanism is obvious in this case, we will emphasize it as a motivation for the later extension. We will work in a neighborhood of the boundaries of the above four pieces.

Firstly, it should be noticed that we can work with the following couple of curves:

- a time-like curve $\alpha : (-\delta, \delta) \longrightarrow \mathcal{R}$, $\alpha(s) = (f_\alpha(s), 0, s) = (-s^2, 0, s)$, and
- a space-like curve $\beta : (-\delta, \delta) \longrightarrow \mathcal{Q}$, $\beta(s) = (f_\beta(s), s, 0) = (s^2, s, 0)$.

They are defined as graphs for a certain $\delta \in (0, 1/2)$. In addition, we have a gluing smooth function, $F : \{(y, z) \in \mathbb{R}^2 \,:\, |z^2 - y^2| < \delta^2\} \longrightarrow \mathbb{R}$, defined as

$$F(y,z) = \left\{ \begin{array}{lll} f_\alpha\left(\operatorname{sign}(z)\sqrt{z^2-y^2}\right) = y^2 - z^2 & \text{if} & z^2 \geq y^2, \\ f_\beta\left(\operatorname{sign}(y)\sqrt{y^2-z^2}\right) = y^2 - z^2 & \text{if} & y^2 \geq z^2. \end{array} \right\}$$

When we consider the four pieces altogether, the Monge parametrization is just obtained in terms of F.

Example 2 : A one-sheet hyperboloid. We consider the following one-sheet hyperboloid

$$\mathbf{H} = \{(x, y, z) \in \mathbb{L}^3 \,:\, x^2 + y^2 - z^2 = 1\}.$$

Clearly, it is $\mathbf{A}_2$-invariant and it is not contained in any fundamental region. In fact, the intersection of **H** and the fundamental regions consists of six connected pieces. We denote by $p = (1, 0, 0)$ and $q = (-1, 0, 0)$ the two points in which **H** intersects the axis. Then, it is easy to check that the boundaries of above six pieces are just the eight light-like orbits with boundary either p or q. Thus, it is necessary to glue twice to obtain **H**.

Firstly, we work around p. We choose δ satisfying $0 < \delta < 1$ and we define:

- a time-like curve $\alpha_p : (-\delta, \delta) \to \mathcal{R}$, $\alpha_p(s) = (f_{\alpha_p}(s), 0, s) = (+\sqrt{1+s^2}, 0, s)$, and
- a space-like curve $\beta_p : (-\delta, \delta) \to \mathcal{Q}$, $\beta_p(s) = (f_{\beta_p}(s), s, 0) = (+\sqrt{1-s^2}, s, 0)$,

which satisfy $\alpha_p(0) = \beta_p(0) = p$. Then, we define the gluing smooth function $\mathbf{F_p} : \{(y, z) \in \mathbb{R}^2 \,:\, |z^2 - y^2| < \delta^2\} \longrightarrow \mathbb{R}$ as

$$\mathbf{F_p}(y,z) = \left\{ \begin{array}{lll} f_{\alpha_p}\left(\operatorname{sign}(z)\sqrt{z^2-y^2}\right) = +\sqrt{1-y^2+z^2} & \text{if} & z^2 \geq y^2, \\ f_{\beta_p}\left(\operatorname{sign}(y)\sqrt{y^2-z^2}\right) = +\sqrt{1-y^2+z^2} & \text{if} & y^2 \geq z^2. \end{array} \right\}$$

Now, in terms of this gluing function, we can define a parametrization of the one-sheet hyperboloid around p as follows

$$\mathrm{X_p} : \{(y, z) \in \mathbb{R}^2 \,:\, |z^2 - y^2| < \delta^2\} \longrightarrow \mathbf{H} \subset \mathbb{L}^3,$$

$$\mathrm{X_p}(y, z) = (\mathbf{F_p}(y, z), y, z) = \left(+\sqrt{1 - y^2 + z^2}, y, z\right).$$

Finally, using the negative square root we obtain curves and a gluing function to paste the pieces around q.

Saddle surface

One-sheet hyperboloid

5.4 Dissection of an $\mathbf{A}_2$-invariant Lorentzian surface

Along this subsection, we assume that M is a connected smooth surface and $\phi : M \longrightarrow \mathbb{L}^3$ is an immersion such that $(M, \phi^*(g))$ is Lorentzian and $\phi(M)$ is $\mathbf{A}_2$-invariant. We are going to use surgery to study the pieces of $\phi(M)$ that lie in each of the fundamental regions and in $\mathcal{P}^+_+ \bigcup \mathcal{P}^-_+ \bigcup \mathcal{P}^+_- \bigcup \mathcal{P}^-_-$. The following assertions can be checked by the reader.

1. $\phi(M) \bigcap (\mathcal{R}^+ \bigcup \mathcal{R}^-)$ is empty or it is a countable union of Lorentzian fundamental surfaces that are generated by time-like curves immersed in either $\tilde{\mathcal{R}}^+$ or $\tilde{\mathcal{R}}^-$, i.e.,

$$\left(\bigcup_{e \in \mathcal{E}} \Sigma_{\alpha_e} \right) \bigcup \left(\bigcup_{f \in \mathcal{F}} \Sigma_{\alpha_f} \right),$$

   where $\{\alpha_e : e \in \mathcal{E}\}$ and $\{\alpha_f : f \in \mathcal{F}\}$ are countable families of time-like curves in $\tilde{\mathcal{R}}^+$ and $\tilde{\mathcal{R}}^-$, respectively.

2. $\phi(M) \bigcap (\mathcal{Q}^+ \bigcup \mathcal{Q}^-)$ is empty or it is a countable union of Lorentzian fundamental surfaces with profile curves immersed in either $\tilde{\mathcal{Q}}^+$ or $\tilde{\mathcal{Q}}^-$, i.e.,

$$\left(\bigcup_{\lambda \in \Lambda} \Sigma_{\beta_\lambda} \right) \bigcup \left(\bigcup_{\theta \in \Theta} \Sigma_{\beta_\theta} \right),$$

   where $\{\beta_\lambda : \lambda \in \Lambda\}$ and $\{\beta_\theta : \theta \in \Theta\}$ are countable families of curves in $\tilde{\mathcal{Q}}^+$ and $\tilde{\mathcal{Q}}^-$, respectively.

3. $\phi(M) \bigcap \left(\mathcal{P}^+_+ \bigcup \mathcal{P}^-_+ \bigcup \mathcal{P}^+_- \bigcup \mathcal{P}^-_-\right)$ is empty or a countable set of light-like orbits lying in the boundary of the Lorentzian fundamental surfaces mentioned in the previous items.

We have already studied the Lorentzian fundamental surfaces, so we will focus on the case in which $\phi(M)$ is not a fundamental surface. So, we assume that $\phi(M)\cap(\mathcal{R}^{+}\cup\mathcal{R}^{-})\neq\emptyset$ and $\phi(M)\cap(\mathcal{Q}^{+}\cup\mathcal{Q}^{-})\neq\emptyset$.

Once we have made the dissection, we will study the curves immersed in $\mathcal{R}$, the curves immersed in $\mathcal{Q}$ and finally, how these curves are related.

Generating curves immersed in $\mathcal{R}$

By using a connection argument, as well as the non existence of closed time-like curves in $\mathcal{R}$, we can state the following facts about the curves in $\tilde{\mathcal{R}}^{+}$ and $\tilde{\mathcal{R}}^{-}$:

[R1] For each $\alpha\in\{\alpha_e : e\in\mathcal{E}\}\cup\{\alpha_f : f\in\mathcal{F}\}$, there exists $U_\alpha\subseteq M$ connected submanifold such that $\phi(U_\alpha)=\Sigma_\alpha$. Moreover, if there exist more than one of such submanifolds, we include in $\{\alpha_e : e\in\mathcal{E}\}\cup\{\alpha_f : f\in\mathcal{F}\}$ as many copies of α as existing submanifolds, and we notate them with different subindices.

[R2] If $\alpha\in\{\alpha_e : e\in\mathcal{E}\}\cup\{\alpha_f : f\in\mathcal{F}\}$, then α is maximal in the sense that there are no connected submanifolds satisfying $U_\alpha\subseteq V$ and $\phi(V)$ do not intersect $\langle\vec{x}\rangle$.

[R3] Many curves of $\{\alpha_e : e\in\mathcal{E}\}\cup\{\alpha_f : f\in\mathcal{F}\}$ can be glued to obtain smooth or piecewise smooth time-like curves in $\mathcal{R}$. Indeed, given $p\in\langle\vec{x}\rangle$, if there exist $e\in\mathcal{E}$ and $f\in\mathcal{F}$ satisfying

- p belongs to the boundary of these two curves, and
- there exists $U\subseteq M$ open and connected, such that $U\cap\phi^{-1}(\mathcal{R}^{+})=U_{\alpha_e}$ and $U\cap\phi^{-1}(\mathcal{R}^{-})=U_{\alpha_f}$,

then these two curves can be glued. If $p\in\phi(M)$, then the union is a time-like smooth curve in $\mathcal{R}$. Otherwise, the union is time-like and smooth everywhere except in p, where we only know it is continuous.

It is easy to check that this procedure cannot be applied to two curves of $\{\alpha_e : e\in\mathcal{E}\}$ or two curves of $\{\alpha_f : f\in\mathcal{F}\}$, because we will not obtain a Lorentzian surface.

[R4] After all the possible gluing processes, we obtain a countable family of continuous piecewise smooth time-like curves in $\mathcal{R}$, $\{\alpha_i : \mathrm{J}_i\longrightarrow\mathbb{R} : i\in\mathcal{I}\}$, $\mathrm{J}_i\subseteq\mathbb{R}$ being an interval for all $i\in\mathcal{I}$ (they are smooth everywhere, except in those points satisfying $p\notin\phi(M)$ and $p\in\langle\vec{x}\rangle$).

[R5] As $\mathcal{R}$ is a Lorentzian plane, we can deduce that for each $i\in\mathcal{I}$ there exists a unique $s_i\in\mathrm{Closure}(\mathrm{J}_i)$ such that $p_i=\lim_{s\to s_i}\alpha(s)$ belongs to $\langle\vec{x}\rangle$. In addition, either s_i belongs to the boundary of J_i, or the curve changes from one fundamental region to another at p_i.

Generating curves immersed in $\mathcal{Q}$

The following assertions hold:

- [Q1] The properties analogous to [R1], [R2] and [R3] hold true for curves in $\{\beta_\lambda : \lambda \in \Lambda\} \cup \{\beta_\theta : \theta \in \Theta\}$.
- [Q2] After all the possible gluing processes, we obtain only one continuous, piecewise smooth curve in $\mathcal{Q}$ (smooth everywhere except in the intersections with $\langle \vec{x} \rangle$, in which we only know the curve is continuous). We will notate this curve as β. This property is a consequence of the connectedness of M and [R5].
- [Q3] The domain of β, J, can be an interval or $\mathbb{S}^1$. The firs situation corresponds to the case in which either β is not closed, or β is closed but there are two curves in $\{\beta_\lambda : \lambda \in \Lambda\} \cup \{\beta_\theta : \theta \in \Theta\}$ that suffered only one gluing process.
- [Q4] Each time β intersects $\langle \vec{x} \rangle$, either the curve changes from a fundamental region to another, or the intersection is a boundary point of β, or the point belongs to the only two curves in $\{\beta_\lambda : \lambda \in \Lambda\} \cup \{\beta_\theta : \theta \in \Theta\}$ that suffered only one gluing process.

Connecting profile curves with different causal character

At this point, we know that the surface $\phi(M)$ is generated by $\{\alpha_i : i \in \mathcal{I}\}$ and β. However, we need a deeper understanding of the relation between β and the curves $\{\alpha_i : i \in \mathcal{I}\}$, as well as the way of constructing the original surface from the generating curves.

Thanks to the connectedness of M, the Remark 5.3 and the properties above, is easy to check the following assertions.

P1. $\forall s_o \in \mathrm{J}$ such that $\beta(s_o) \in \langle \vec{x} \rangle$, there exist $\varepsilon > 0$ and $i \in \mathcal{I}$, satisfying

- $\beta(s_o) \in \mathrm{Closure}(\mathrm{trace}(\alpha_i))$, and
- $\Sigma_{\beta_{|\mathrm{J}_o}} \bigcup \Sigma_{\alpha_i}$ is a smooth surface, where $\mathrm{J}_o =]s_o - \varepsilon, s_o + \varepsilon[\cap \mathrm{J}$.

Roughly speaking, for each $s_o \in \mathrm{J}$ such that $\beta(s_o) \in \langle \vec{x} \rangle$, there exists α_i gluing appropriately with β in a neighborhood of s_o.

P2. $\forall i \in \mathcal{I}$, there exist $\varepsilon > 0$ and $s_o \in \mathrm{Closure}(\mathrm{J})$, such that

- $\lim_{s \to s_o} \beta(s) = \lim_{s \to s_i} \alpha(s)$, and
- $\Sigma_{\beta_{|\mathrm{J}_o}} \bigcup \Sigma_{\alpha_i}$ is a smooth surface, where $\mathrm{J}_o =]s_o - \varepsilon, s_o + \varepsilon[\cap \mathrm{J}$.

Roughly speaking, for each α_i, there exists $s_o \in \mathrm{Closure}(\mathrm{J})$ such that β and α_i glue appropriately in a neighborhood of s_o.

Remark 5.6 *If we ask* $U_{\alpha_i^+} \cup U_{\alpha_i^-} \cup U_{\beta_i^+} \cup U_{\beta_i^-}$ *to be connected, being* $\alpha_i^\pm = \alpha_i|_{\mathrm{J}_i \cap \mathbb{R}^\pm}$ *and* $\beta^\pm = \beta|_{\mathrm{J}_o \cap \mathbb{R}^\pm}$*, then* i *is unique in* **P1***, and* s_o *is unique in* **P2***. In this case,* **P1** *and* **P2** *can be viewed as injective maps,* $\mathbf{P1} : \{s_o \in \mathrm{J} : \beta(s_o) \in \langle \vec{x} \rangle\} \longrightarrow \mathcal{I}$ *and* $\mathbf{P2} : \mathcal{I} \longrightarrow \{s_o \in \mathrm{Closure}(\mathrm{J}) : \lim_{s \to s_o} \beta(s) \in \langle \vec{x} \rangle\}$*, verifying* $\mathbf{P2} \circ \mathbf{P1}(s) = s$ *for all* $s \in \mathrm{J}$ *such that* $\beta(s) \in \langle \vec{x} \rangle$*.*

Remark 5.7 *When considering* $\Sigma_{\beta_{|\mathrm{J}_o}} \cup \Sigma_{\alpha_i}$*, we are also adding the light-like orbits belonging to the boundary of these two surfaces and to* $\phi(M)$ *(otherwise the union will not be connected).*

Light-like orbits connecting the pieces

Definition 5.8 *Given any point* $p = (x_o, 0, 0) \in \langle \vec{x} \rangle$*, we define the* light-like orbital *at* p*,* $\mathbf{O}_p$*, as the set consisting of* p *together with the four light-like orbits through this point, i.e.* $\mathbf{O}_p = \{(x_o, y, z) : y^2 = z^2\}$*.*

Definition 5.9 *For each* $s_o \in \mathrm{Closure}(\mathrm{J})$ *such that* $p = \lim_{s \to s_o} \beta(s) \in \langle \vec{x} \rangle$*, we define the* light-like patch *at* s_o *as*

$$B_{s_o} = \mathbf{O}_{p_o} \bigcap \phi(U),$$

where $p_o = \lim_{s \to s_o} \beta(s)$ *and* $U \subseteq M$ *is a domain such that:*

- $\phi(U) \bigcap (\mathcal{Q}^+ \bigcup \mathcal{Q}^-) = \Sigma_{\beta_{|\mathrm{J}_o}}$*, and*

Remark 5.10 *The light-like patch at* s_o *is just the union of the elements of a subset of* $\{\{p_o\}, \{(x_o, a, a) : a > 0\}, \{(x_o, a, a) : a < 0\}, \{(x_o, -a, a) : a > 0\}, \{(x_o, -a, a) : a < 0\}\}$ *where* $p_o = (x_o, 0, 0) = \lim_{s \to s_o} \beta(s)$*.*

Summary of the dissection

Given an $\mathbf{A}_2$-invariant Lorentzian immersion, $\phi : M \longrightarrow \mathbb{L}^3$, there exists a family of time-like curves in $\mathcal{R}$, $\{\alpha_i : \mathrm{J}_i \subseteq \mathbb{R} \longrightarrow \mathcal{R} : i \in \mathcal{I}\}$, and a curve in $\mathcal{Q}$, $\beta : \mathrm{J} \longrightarrow \mathcal{Q}$, satisfying:

- All of them are smooth everywhere except in those points belonging to $\langle \vec{x} \rangle \backslash \phi(M)$, in which the curve is only known to be continuous.
- For each $i \in \mathcal{I}$, J_i is an interval. Even more, there exists only one $s_i \in \mathrm{Closure}(\mathrm{J}_i)$ such that $p_i = \lim_{s \to s_i} \alpha(s)$ belongs to $\langle \vec{x} \rangle$. If s_i is not a boundary point of J_i, then it is a point in which the curve goes from one fundamental region into another.
- The domain of β, J, is either an interval, or $\mathbb{S}^1$, see [Q3].
- Each time β intersects $\langle \vec{x} \rangle$, either the curve goes from one fundamental region to another, or the point belongs to $\{\lim\limits_{s \to s_o} \beta(s) \,/\, s_o \in \partial \mathrm{J}\}$.

- **P1** and **P2** hold.

Also, for each $s_o \in \text{Closure(J)}$ such that $\lim_{s\to s_o}\beta(s) \in \langle\vec{x}\rangle$, there exists a set, B_{s_o}, called light-like patch, consisting of the union of some of the following sets: $\{p_o\}$, $\{(x_o,a,a) : a>0\}$, $\{(x_o,a,a) : a<0\}$, $\{(x_o,-a,a) : a>0\}$ and $\{(x_o,-a,a) : a<0\}$ (where $p_o=(x_o,0,0)=\lim_{s\to s_o}\beta(s)$).

In this setting,

$$\phi(M)=\Sigma_\beta \bigcup \left(\bigcup_{i\in\mathcal{I}}\Sigma_{\alpha_i}\right)\bigcup\left(\bigcup\{B_{s_o} : \lim_{s\to s_o}\beta(s)\in\langle\vec{x}\rangle\}\right).$$

Note that Σ_{α_i} and Σ_β correspond to Definition 5.2, but here we are removing the points of the axis. From now on, we will use this assumption freely.

5.5 Characterization of the gluing

In this subsection, we characterize the way to paste two Lorentzian fundamental symmetric surfaces, Σ_α and Σ_β, which are generated by suitable curves, α in $\mathcal{R}$ and β in $\mathcal{Q}$.

Let α be a time-like curve in $\mathcal{R}$ and β a curve in $\mathcal{Q}$, such that $\lim_{s\to 0}\alpha(s)=\lim_{s\to 0}\beta(s)=p=(x_o,0,0)\in\langle\vec{x}\rangle$. Firstly, we choose an appropriate light-like patch, $B_0\subset \mathbf{O}_p=\{(x_o,y,z) : y^2=z^2\}$. Secondly, we take a neighborhood of 0 in the domain of β such that $\lim_{s\to\tilde{s}}\beta(s)\notin\langle\vec{x}\rangle$, for $\tilde{s}\neq s_o$. There is no loss of generality, because only that neighborhood is important in the gluing process.

In this setting, the following result can be regarded as the master piece to understand how $\mathbf{A}_2$-invariant surfaces generated by curves glue smoothly. Moreover, it characterizes the gluing mechanism.

Theorem 5.11 ***Local Gluing Theorem*** *In the setting of this subsection,* Σ_α *and* Σ_β *glue smoothly and the metric along the union is Lorentzian, i.e.* $\Sigma=\Sigma_\alpha\bigcup\Sigma_\beta\bigcup B_0$ *is a smooth Lorentzian surface in a neighborhood of* B_0*, if, and only if, there exist smooth functions* f_α *and* f_β *such that the following assertions hold:*

LG1. $\alpha(u)=(f_\alpha(u),0,u)$ *is a parametrization of* α *in a neighborhood of* p*.*

LG2. $\beta(u)=(f_\beta(u),u,0)$ *is a parametrization of* β *in a neighborhood of* p*.*

LG3. The following function is smooth

$$F(y,z)=\left\{\begin{array}{lll} f_\alpha\left(sign(z)\sqrt{z^2-y^2}\right) & if & z^2\geq y^2, \\ f_\beta\left(sign(y)\sqrt{y^2-z^2}\right) & if & y^2\geq z^2, \end{array}\right\},$$

defined on a neighborhood of $\{(y,z) : (x_o,y,z)\in B_0\}$*. F is called the* ***gluing function****.*

Proof: Assume that Σ is a smooth Lorentzian surface in a neighborhood of B_0. We split the proof of the necessary condition in two cases.

Case 1: If both α and β do not cross the axis, each of them is contained in the union of a fundamental region and the axis. We can assume that trace$(\alpha) \subseteq \tilde{\mathfrak{R}}^+ \bigcup \langle \vec{x} \rangle$ and trace$(\beta) \subseteq \tilde{\mathfrak{Q}}^+ \bigcup \langle \vec{x} \rangle$, since the proof for other cases works similarly.

We prove *LG1*.

The curve α can be written down as $\alpha(s) = (\alpha_1(s), 0, \alpha_3(s))$, and we can assume it is arclength parametrized. Then, $\alpha_3'(s)^2 = \alpha_1'(s)^2 + 1 > 0$. Thus, by using the Inverse Function Theorem, we obtain $\rho > 0$ such that $\alpha_3 :]0, \rho[\longrightarrow \alpha_3(]0, \rho[)$ is a diffeomorphism. Now, from $\lim_{s \to 0} \alpha_3(s) = 0$ and $\alpha_3 > 0$, we get that $\alpha_3(]0, \rho[) =]0, \varrho[$ for certain $\varrho > 0$. This provides a smooth function $f_\alpha :]0, \varrho[\longrightarrow \mathbb{R}$, defined by $f_\alpha(u) = \alpha_1 \circ \alpha_3^{-1}(u)$, and so LG1 holds.

We prove *LG2*.

We can write down β as $\beta(s) = (\beta_1(s), \beta_2(s), 0)$, and we can assume this parametrization is arc-length. Then, we consider

$$X_\beta(s,t) := \xi_t(\beta(s)).$$

Our main aim is to show that $\lim_{s \to 0} \beta_2'(s) \neq 0$. Suppose, contrary to our claim, that $\lim_{s \to 0} \beta_2'(s) = 0$.

It should be noticed that the light-like orbit $\{(x_o, y, y) \in \mathbb{L}^3 / y > 0\}$ is contained in B_0. Given a point in that orbit, $q = (x_o, a, a)$ with $a > 0$, let $\gamma_q(\tau) = X_\beta(s_q(\tau), t_q(\tau))$ be a smooth curve with $\lim_{\tau \to 0} \gamma_q(\tau) = q$. Obviously, this implies that $\lim_{\tau \to 0} s_q(\tau) = 0$. As $\lim_{s \to 0} \beta_2(s) = 0$, then

$$\lim_{\tau \to 0} \cosh(t_q(\tau)) = \lim_{\tau \to 0} \sinh(t_q(\tau)) = +\infty. \tag{6}$$

On the other hand, we compute the Riemannian normal to Σ along γ_q, obtaining

$$N_R(\gamma_q(\tau)) = \frac{(\beta_2'(s_q(\tau)), -\beta_1'(s_q(\tau)) \cosh(t_q(\tau)), \beta_1'(s_q(\tau)) \sinh(t_q(\tau)))}{\sqrt{\beta_2'(s_q(\tau))^2 + \beta_1'(s_q(\tau))^2 (\cosh^2(t_q(\tau)) + \sinh^2(t_q(\tau)))}}.$$

Now, by using that $\lim_{s \to 0} \beta_2'(s) = 0$, as well as (6) and the previous expression, we obtain

$$N_R(q) = \lim_{\tau \to 0} N_R(s_q(\tau), t_q(\tau)) = (0, -\frac{1}{\sqrt{2}}, \frac{1}{\sqrt{2}}).$$

This implies that $T_q\Sigma$ is a degenerate plane, which provides a contradiction. Therefore, we have proven that $\lim_{s \to 0} \beta_2'(s) \neq 0$. Now, we can follow a similar argument to the one used with α, concluding that LG2 holds.

We prove *LG3*.

We define the following sets

$$\begin{aligned}\Omega &= \{(y,z)\in\mathbb{R}^2 : |z^2-y^2|<\varrho^2, (x_o,y,z)\in\mathcal{R}^+\cup\mathcal{Q}^+\cup B_0\},\\ \Omega_\alpha &= \{(y,z)\in\mathbb{R}^2 : |z^2-y^2|<\varrho^2, (x_o,y,z)\in\mathcal{R}^+\}, \text{ and}\\ \Omega_\beta &= \{(y,z)\in\mathbb{R}^2 : |z^2-y^2|<\varrho^2, (x_o,y,z)\in\mathcal{Q}^+\},\end{aligned}$$

ϱ being the minimum of $\{\varrho_\alpha, \varrho_\beta\}$. It is clear that $F_{|\Omega_\alpha}$ and $F_{|\Omega_\beta}$ are smooth. In order to study the smoothness of F at the points of B_0, we define $\Sigma' = \Sigma_{\alpha_{|]0,\varrho[}} \cup \Sigma_{\beta_{|]0,\varrho[}} \cup B_0$ and the map $\Pi : \Sigma' \longrightarrow \Omega$, $\Pi(x,y,z)=(y,z)$. Π is smooth, bijective and $\Pi^{-1}(y,z)=(F(y,z),y,z)$. If we prove that $d\Pi_q$ is bijective $\forall q\in B_0$, the Inverse Function Theorem gives us the smoothness of F at the points of B_0. It is enough to prove that $\partial_x(q)\notin T_q\Sigma'$ $\forall q\in B_0$. To do so, we distinguish three cases:

- If $q=p$, then $\{(x_o,y,-y)\in\mathbb{L}^3/y\in\mathbb{R}\}\subseteq B_0$, and so, $T_q\Sigma' = \mathrm{Span}\{\partial_y(q)+\partial_z(q), \partial_y(q)-\partial_z(q)\}$.
- If $q\in\{(x_o,y,y)\in\mathbb{L}^3/y\neq 0\}$, it is clear that $\partial_y(q)+\partial_z(q)\in T_q\Sigma'$. As $T_q\Sigma'$ is a Lorentzian plane, and $\mathrm{Span}\{\partial_x(q), \partial_y(q)+\partial_z(q)\}$ is a degenerate plane, we get $\partial_x(q)\notin T_q\Sigma'$.
- If $q\in\{(x_o,y,-y)\in\mathbb{L}^3/y\neq 0\}$, we proceed similarly to the previous item.

Case 2: At least one of the curves α and β crosses the axis.

From Case 1, conditions LG1, LG2 and LG3 hold except for the smoothness of f_α and f_β at $u=0$, and the smoothness of F at $(0,0)$ (in the case that they make sense).

We will only prove the smoothness of f_α, since the proof for f_β is analogous.

If either $\Sigma_\alpha\cap\mathcal{R}^+=\emptyset$ or $\Sigma_\alpha\cap\mathcal{R}^-=\emptyset$, the proof is trivial. Consequently, consider that $\Sigma_\alpha\cap\mathcal{R}^+\neq\emptyset$ and $\Sigma_\alpha\cap\mathcal{R}^-\neq\emptyset$. Then, either $\Sigma_\beta\cap\mathcal{Q}^+\neq\emptyset$ or $\Sigma_\beta\cap\mathcal{Q}^-\neq\emptyset$. Without loss of generality, we may assume that $\Sigma_\beta\cap\mathcal{Q}^+\neq\emptyset$. Given $a>0$, we choose the following curves, that are smooth because of Case 1:

$$\gamma_1(t) = \Big(F(a-\frac{t}{4a}, a+\frac{t}{4a}), a-\frac{t}{4a}, a+\frac{t}{4a}\Big) = \left\{\begin{array}{ll} \big(f_\alpha(\sqrt{t}), a-\frac{t}{4a}, a+\frac{t}{4a}\big) & \text{if } t\geq 0\\ \big(f_\beta(\sqrt{-t}), a-\frac{t}{4a}, a+\frac{t}{4a}\big) & \text{if } t\leq 0\end{array}\right\},$$

$$\gamma_2(t) = \Big(F(a-\frac{t}{4a}, -a-\frac{t}{4a}), a-\frac{t}{4a}, -a-\frac{t}{4a}\Big) = \left\{\begin{array}{ll} \big(f_\alpha(-\sqrt{t}), a-\frac{t}{4a}, -a-\frac{t}{4a}\big) & \text{if } t\geq 0\\ \big(f_\beta(\sqrt{-t}), a-\frac{t}{4a}, -a-\frac{t}{4a}\big) & \text{if } t\leq 0\end{array}\right\}.$$

Then, we have

$$\lim_{\substack{t\to 0\\ t>0}} \frac{d^n}{dt^n}\Big(f_\alpha(\sqrt{t})\Big) = \lim_{\substack{t\to 0\\ t<0}} \frac{d^n}{d^nt}\big(f_\beta(\sqrt{-t})\big) = \lim_{\substack{t\to 0\\ t>0}} \frac{d^n}{dt^n}\Big(f_\alpha(-\sqrt{t})\Big) \quad \forall n\in\mathbb{N},$$

and consequently

$$\lim_{\substack{u\to 0\\ u>0}} \frac{d^n}{du^n} f_\alpha(u) = \lim_{\substack{u\to 0\\ u<0}} \frac{d^n}{du^n} f_\alpha(u) \quad \forall n\in\mathbb{N}.$$

Thanks to Case 1, we can assure that the gluing function is smooth everywhere except at $(0,0)$. The smoothness of F at $(0,0)$ is obtained by applying the Inverse Function Theorem to Π at p.

Let us prove the converse. We suppose that LG1, LG2 and LG3 hold. It is enough to show that Σ is a Lorentzian smooth surface in a neighborhood of B_0. Indeed, as the function F can be used to define a parametrization of Σ in a neighborhood of B_0, we only need to exhibit the Lorentzian character of the surface along B_0.

Firstly, we need to prove that $f'_\alpha(0) = f'_\beta(0) = 0$. If $p \in \Sigma$, then the proof is trivial. Otherwise, we have to prove that if any of those two equalities do not hold, then F is not smooth. We know that B_0 contains at least one orbit of the light-like orbital $\mathbf{O}_p$. We suppose $\{(x_o, y, y) \in \mathbb{L}^3 / y > 0\} \subseteq B_0$ and we consider $\{(y, y) \,/\, y > 0\}$. It is easy to see that the gradient of F is not continuous along $\{(y, y) \,/\, y > 0\}$ when any of the equalties $f'_\alpha(0) = f'_\beta(0) = 0$ are not true. This is a contradiction because F is a smooth function.

Secondly, we prove the surface along B_0 is Lorentzian. If $p \in B_0$, then $T_p\Sigma = \mathrm{Span}\{\lim_{s\to 0} \alpha'(s) = (0,0,1), \lim_{s\to 0} \beta'(s) = (0,1,0)\}$, which is Lorentzian. Next, we focus on studying the metric along the light-like orbits contained in B_0. If we suppose $\{(x_o, y, y) \in \mathbb{L}^3 / y > 0\} \subseteq B_0$, then either $\Sigma_\alpha \cap \mathcal{R}^+ \neq \emptyset$ or $\Sigma_\beta \cap \mathcal{Q}^+ \neq \emptyset$. We assume the first one holds and we take (x_o, a, a) with $a > 0$. Now, choose the curve $\omega(t) = (F(at, a), at, a)$ for $t \leq 1$. Certainly, $\omega(1) = (x_o, a, a)$ and so, using that $f'_\alpha(0) = 0$, we compute $\omega'(1) = (-a^2 f''_\alpha(0), a, 0)$. Then, the vector

$$\frac{-2}{a(1 + a^2(f''_\alpha(0))^2)}\omega'(1) + (0,1,1)$$

is light-like, it belongs to $T_{(x_o,a,a)}\Sigma$ and it is not proportional to $(0,1,1)$, so $T_{(x_o,a,a)}\Sigma$ is a Lorentzian plane.

The proof for the other light-like orbits is analogous. □

Remark. It should be noticed that we have shown that $f'_\alpha(0) = f'_\beta(0) = 0$ when F is smooth. Then, α and β are perpendicular to $\langle \vec{x} \rangle$, and so, there cannot exist a singularity at p. Another consequence of this fact is that for each $\mathbf{A}_2$-invariant immersion, the curves $\{\alpha_i : i \in \mathcal{I}\} \cup \{\beta\}$ are smooth.

5.6 Classification of Lorentzian $\mathbf{A}_2$-invariant surfaces

As a summary of all the results obtained along the previous subsections, we exhibit the classification of Lorentzian $\mathbf{A}_2$-invariant surfaces. As a previous step, we need the following definition.

Definition 5.12 *Let*

$$\{\beta : \mathrm{J} \to \mathcal{Q}\} \bigcup \{\alpha_i : \mathrm{J}_i \to \mathcal{R} \,:\, i \in \mathcal{I}\}$$

be a countable family of smooth curves such that α_i is time-like and $\mathrm{J}_i \subseteq \mathbb{R}$ is an interval $\forall i \in \mathcal{I}$, and J is either an interval or $\mathbb{S}^1$. We will say that these curves are in general position *if they satisfy the following three conditions:*

P1. $\forall s \in \mathrm{J}$ *such that* $\beta(s) \in \langle \vec{x} \rangle$, *there exist* $\varepsilon > 0$ *and* $i \in \mathcal{I}$ *satisfying*

- $\beta(s) \in \mathrm{Closure}(\mathrm{trace}(\alpha_i))$, *and*
- $\Sigma_{\beta_{|\mathrm{J}_o}} \bigcup \Sigma_{\alpha_i}$ *is a smooth surface, where* $\mathrm{J}_o =]s_o - \varepsilon, s_o + \varepsilon[\cap \mathrm{J}$.

P2. $\forall i \in \mathcal{I}$, *there exist* $\varepsilon > 0$ *and* $s_o \in \mathrm{Closure}(\mathrm{J})$ *such that*

- $\lim_{s \to s_o} \beta(s) \in \mathrm{Closure}(\mathrm{trace}(\alpha_i))$, *and*
- $\Sigma_{\beta_{|\mathrm{J}_o}} \bigcup \Sigma_{\alpha_i}$ *is smooth, where* $\mathrm{J}_o =]s_o - \varepsilon, s_o + \varepsilon[\cap \mathrm{J}$.

P3. *Using* **P1** *and* **P2**, *there can be defined two injective maps,*

$$\mathbf{P1} : \{s \in \mathrm{J} : \beta(s) \in \langle \vec{x} \rangle\} \longrightarrow \mathcal{I} \text{ and } \mathbf{P2} : \mathcal{I} \longrightarrow \{s_o \in \mathrm{Closure}(\mathrm{J}) : \lim_{s \to s_o} \beta(s) \in \langle \vec{x} \rangle\},$$

verifying $\mathbf{P2}(\mathbf{P1}(s)) = s$ *for all* $s \in \mathrm{J}$ *such that* $\beta(s) \in \langle \vec{x} \rangle$.

Remark 5.13 *In the previous definition, when we say* $\Sigma_{\beta_{|\mathrm{J}_o}} \bigcup \Sigma_{\alpha_i}$ *is smooth, it means that* $\Sigma_{\beta_{|\mathrm{J}_o}} \bigcup \Sigma_{\alpha_i}$ *joint to an appropriate* $\mathbf{A}_2$*-invariant subset of* $\mathbf{O}_{\beta(s)}$ *is smooth.*

Theorem 5.14 *Let* M *be a connected surface and* $\phi : M \longrightarrow \mathbb{L}^3$ *an immersion. Then,* $(M, \phi^*(g))$ *is Lorentzian and* $\mathbf{A}_2$*-invariant if and only if either*

1. $\phi(M)$ *is a Lorentzian fundamental symmetric surface (described in Theorem 5.5), or the union of such surface and one, two, three or four light-like orbits.*
2. $\phi(M)$ *is the union of the rotational surfaces generated by a family of curves in general position,*

   $$\{\beta : \mathrm{J} \to \mathcal{Q}\} \cup \{\alpha_i : \mathrm{J}_i \to \mathcal{R} \, : \, i \in \mathcal{I}\},$$

   and the corresponding family of light-like patches,

   $$\{B_{s_o} : \lim_{s \to s_o} \beta(s) \in \langle \vec{x} \rangle\};$$

   that is

   $$\phi(M) = \Sigma_\beta \bigcup \left(\bigcup_{i \in \mathcal{I}} \Sigma_{\alpha_i} \right) \bigcup \left(\bigcup \{B_{s_o} : \lim_{s \to s_o} \beta(s) \in \langle \vec{x} \rangle\} \right).$$

5.7 An algorithm to construct $\mathbf{A}_2$-invariant Lorentzian surfaces not contained in any fundamental region

To finish the study of $\mathbf{A}_2$-invariant Lorentzian surfaces, we give an algorithm to construct many examples of this kind of surfaces, that are not contained in any fundamental region.

1. Given $\delta > 0$, choose a smooth function $\varphi : (-\delta^2, \delta^2) \longrightarrow \mathbb{R}$.

2. We consider the functions $f_\alpha : \mathrm{J}_\alpha \subseteq (-\delta, \delta) \longrightarrow \mathbb{R}$ and $f_\beta : \mathrm{J}_\beta \subseteq (-\delta, \delta) \longrightarrow \mathbb{R}$, defined as
$$f_\alpha(s) = \varphi(s^2) \quad \text{and} \quad f_\beta(s) = \varphi(-s^2),$$
where J_α and J_β are intervals such that 0 lies in the closure of both of them and $(f'_\alpha(s))^2 < 1$ for all $s \in \mathrm{J}_\alpha$.

3. We define the following curves, $\alpha : \mathrm{J}_\alpha \longrightarrow \mathcal{R}$ and $\beta : \mathrm{J}_\beta \longrightarrow \mathcal{Q}$, given by
$$\alpha(s) = (f_\alpha(s), 0, s) \quad \text{and} \quad \beta(s) = (f_\beta(s), s, 0).$$

4. Choose $B_0 \subset \{(\varphi(0), y, z) \in \mathbb{L}^3 : y^2 = z^2\}$ to be $\mathbf{A}_2$-invariant and such that $\Sigma_\alpha \cup \Sigma_\beta \cup B_0$ is a topological surface.

5. The surfaces Σ_α and Σ_β, generated by α and β respectively, glue smoothly and $\Sigma = \Sigma_\alpha \bigcup \Sigma_\beta \bigcup B_0$ is an $\mathbf{A}_2$-invariant Lorentzian surface. The gluing function (see Theorem 5.11) is given by
$$F(y, z) = \varphi(z^2 - y^2).$$

In addition, if we start with two functions, f_α and f_β, such that they are analytic in 0, $f_\alpha(0) = f_\beta(0)$ and the corresponding graphs in $\mathcal{R}$ and $\mathcal{Q}$ generate Lorentzian surfaces that glue smoothly with Lorentzian metric along the union (which means that the gluing function F is smooth), then we can show the existence of a smooth function, φ, that allows us to write those graphs as
$$\alpha(s) = (\varphi(s^2), 0, s) \quad \text{and} \quad \beta(s) = (\varphi(-s^2), s, 0).$$
This result constitutes a kind of converse when starting from analytic data.

The following pictures illustrate the last four subsections. Picture A shows a surface touching the axis twice, and crossing all fundamental regions in both cases. Picture B shows a surface touching the axis at three points, crossing four fundamental regions around the first point, three regions around the second point and just one region around the final point.

Picture B

6 First variation of the Willmore functional in a semi-Riemannian manifold

In contrast with the pure rotational case, i. e., the one associated with the group $\mathbf{A}_1$, now, we will use a direct variational approach to study the case of space-like axis. This means we will avoid the principle of symmetric criticality. Thus, it is necessary to obtain the Euler-Lagrange equations associated with the problem $(\mathbf{I}^{\varepsilon}_{\Gamma}(M,\mathbb{L}^3);\mathfrak{S})$ or equivalently $(\mathbf{I}^{\varepsilon}_{\Gamma}(M,\mathbb{L}^3);\mathfrak{W})$. These equations were computed in [39], when the target space was a Riemannian three-space with constant curvature. However, now we have semi-Riemannian target spaces, namely Lorentzian three-spaces. On the other hand, the constancy of the curvature is not enough for our purposes. In fact, we will need to make some suitable conformal changes, in the Lorentz-Minkowski metric, which, obviously, will not preserve the constancy of the curvature. Consequently, the variational setting will be as general as possible and later, computations will be particularized to our purposes. To start with, we introduce some preliminaries following the notation of [39].

Let M be a compact orientable smooth surface with boundary (maybe empty) and $(\bar{\mathsf{M}},\bar{\mathsf{g}})$ a 3-dimensional semi-Riemannian manifold. Let $\phi:\mathsf{M}\to\bar{\mathsf{M}}$ be a non-degenerate immersion. Only in this section, $\mathbf{I}_{\phi(\partial\mathsf{M})}(\mathsf{M},\bar{\mathsf{M}})$ will denote the space of non-degenerate immersions that fix the boundary, $\phi(\partial\mathsf{M})$, without further conditions on the normal field along the common boundary.

A variation of ϕ in $\mathbf{I}_{\phi(\partial\mathsf{M})}(\mathsf{M},\bar{\mathsf{M}})$ is nothing but a smooth map, $\Phi:\mathsf{M}\times(-\delta,\delta)\longrightarrow\bar{\mathsf{M}}$ satisfying the following conditions:

1. For each $v\in(-\delta,\delta)$, the map $\phi_v:\mathsf{M}\longrightarrow\bar{\mathsf{M}}$, defined by $\phi_v(m)=\Phi(m,v)$, belongs to $\mathbf{I}_{\phi(\partial\mathsf{M})}(\mathsf{M},\bar{\mathsf{M}})$, and
2. $\phi_0=\phi$.

It should be noticed that $\phi_v^*(\bar{\mathsf{g}})$ is non-degenerate for any $v\in(-\delta,\delta)$, and $\Phi(m,v)=\phi(m)$, for any $m\in\partial\mathsf{M}$. Now, we can use all the paraphernalia of geometrical objects along a map. In particular, we can talk about vector fields along Φ, or in other words, cross sections of the induced vector bundle $\Phi^*(\mathsf{T}\bar{\mathsf{M}})$ over $\mathsf{M}\times(-\delta,\delta)$. Thus, we can define the following vector field along Φ,

$$\mathbf{V}(m,v)=\Phi_*\left(\frac{\partial}{\partial v}(m,v)\right).$$

In particular, it holds $\mathbf{V}(m,v)=0$, $\forall m\in\partial\mathsf{M}$. This, when restricted to $v=0$, provides a vector field along ϕ which vanishes along $\partial\mathsf{M}$, called the variational vector field

$$\mathbf{V}(m)=\mathbf{V}(m,0)=\Phi_*\left(\frac{\partial}{\partial v}(m,0)\right).$$

Therefore, the tangent space $\mathsf{T}_\phi\left(\mathbf{I}_{\phi(\partial\mathsf{M})}(\mathsf{M},\bar{\mathsf{M}})\right)$ is made up of those vector fields along ϕ that vanish along $\partial\mathsf{M}$.

We consider the Willmore variational problem which is associated with the functional $\mathfrak{W} : \mathbf{I}_{\phi(\partial\mathsf{M})}(\mathsf{M}, \bar{\mathsf{M}}) \longrightarrow \mathbb{R}$ defined by

$$\mathfrak{W}(\psi) = \int_{\mathsf{M}} \left(H_\psi^2 + \mathsf{R}_\psi\right) \, dA_\psi + \int_{\partial\mathsf{M}} \kappa_\psi \, ds,$$

where H_ψ denotes the mean curvature function of (M, ψ), R_ψ is the sectional curvature of the target space, $(\bar{\mathsf{M}}, \bar{\mathsf{g}})$, restricted to the tangent plane $d\psi(\mathsf{TM})$ and κ_ψ is the geodesic curvature of $\partial\mathsf{M}$ in $(\mathsf{M}, \psi^*(\bar{\mathsf{g}}))$. Now, we wish to determine the sufficient and necessary conditions for ϕ to be a critical point of the above functional, in other words, a Willmore surface of the conformal space $(\bar{\mathsf{M}}, [\bar{\mathsf{g}}])$. Therefore, we need to compute the differential of $\mathfrak{W}$ at ϕ, i. e., $\delta\mathfrak{W}(\phi) : \mathsf{T}_\phi\left(\mathbf{I}_{\phi(\partial\mathsf{M})}(\mathsf{M}, \bar{\mathsf{M}})\right) \longrightarrow \mathbb{R}$. Given $\mathbf{V} \in \mathsf{T}_\phi\left(\mathbf{I}_{\phi(\partial\mathsf{M})}(\mathsf{M}, \bar{\mathsf{M}})\right)$, consider a variation $\Phi : \mathsf{M} \times (-\delta, \delta) \longrightarrow \bar{\mathsf{M}}$ with $\mathbf{V}(m) = \mathbf{V}(m, 0) = \Phi_*\left(\frac{\partial}{\partial v}(m, 0)\right)$, $\forall m \in \mathsf{M}$. To simplify the notation, we put $\mathsf{M}_v = (\mathsf{M}, \phi_v^*(\bar{\mathsf{g}}))$, $H_v = H_{\phi_v}$, $\mathsf{R}_v = \mathsf{R}_{\phi_v}$, $\kappa_v = \kappa_{\phi_v}$, $dA_v = dA_{\phi_v}$, and then

$$\delta\mathfrak{W}(\phi)[\mathbf{V}] = \left\{\frac{\partial}{\partial v}\left[\int_{\mathsf{M}_v} \left(H_v^2 + \mathsf{R}_v\right) dA_v + \int_{\partial\mathsf{M}} \kappa_v \, ds\right]\right\}_{v=0}. \tag{7}$$

We will compute this step by step. First, we control the action on the boundary. To do so, we recall that we are using variations that fix the boundary, $\phi(\partial\mathsf{M})$. Let $\{\nu, T\}$ be a unitary positively oriented frame field on $\phi(\partial\mathsf{M})$, where T is tangent to $\phi(\partial\mathsf{M})$ and ν is the outward normal to $\phi(\partial\mathsf{M})$. Since T does not depend on v, $\{\nu^v, T\}$ is the orientation of $\phi(\partial\mathsf{M})$ in $\phi_v(M)$, for each v. Moreover, the principal curvature vector field, $\eta = \bar{\nabla}_T T$, of $\phi(\partial\mathsf{M})$ in $(\bar{\mathsf{M}}, \bar{\mathsf{g}})$, does not depend on v, and so

$$\left\{\frac{\partial}{\partial v}\int_{\partial\mathsf{M}} \kappa_v \, ds\right\}_{v=0} = -\int_{\partial\mathsf{M}} \bar{\mathsf{g}}(\eta, \bar{\nabla}_{\mathbf{V}}\nu^v) ds = -\int_{\partial\mathsf{M}} \bar{\mathsf{g}}\left(\eta^\perp, D_\nu \mathbf{V}^\perp\right) ds, \tag{8}$$

where $\perp$ indicates normal component and D the normal connection of (M, ϕ) in $(\bar{\mathsf{M}}, \bar{\mathsf{g}})$. To obtain the second equality we have used an argument similar to that used in the Riemannian case, [39].

Remark. Regarding (8), it should be noticed that under the boundary conditions we are considering in this paper (i. e., space of surfaces immersed in $\mathbb{L}^3$, with the same causal character, the same boundary and the same Gauss map along the common boundary), $D_\nu \mathbf{V}^\perp = 0$ and so

$$\left\{\frac{\partial}{\partial v}\int_{\partial\mathsf{M}} \kappa_v \, ds\right\}_{v=0} = 0,$$

which is not surprising, because the total curvature of the boundary is a constant under these boundary conditions.

To obtain the variation of the two-dimensional integral appearing in (7), we need some formulae which can be obtained by using standard variational arguments and that we collect in the following

Lemma 6.1 *The following statements hold*

1. *Let* $\mathbf{H}(m,v)$ *be the vector field along the variation* Φ *that measures the mean curvature vector field of* (M,ϕ_v) *at* $m\in\mathsf{M}$*, then*

$$\left\{D_{\frac{\partial}{\partial v}}\mathbf{H}\right\}_{v=0}=\frac{1}{2}\left[\triangle\mathbf{V}^{\perp}+\tilde{A}(\mathbf{V}^{\perp})+\varepsilon Ric(N_\phi,N_\phi)\mathbf{V}^{\perp}\right]+D_{\mathbf{V}^{\top}}\mathbf{H},$$

   where $\triangle$ *is the Laplacian relative to the normal connection,* D*,* $\tilde{A}$ *is the Simons' operator (see [34]), Ric is the Ricci tensor of* $(\bar{\mathsf{M}},\bar{\mathsf{g}})$ *and* $\varepsilon=\bar{\mathsf{g}}(N_\phi,N_\phi)$*.*

2. *The variation of the area element is given by the following formula*

$$\left\{\frac{d}{dv}\left(dA_v\right)\right\}_{v=0}=-2\bar{\mathsf{g}}(\mathbf{H},\mathbf{V})\,dA+d\theta,$$

   where $dA=dA_0$ *and* θ *is the one-form defined by* $\theta(Z)=dA(\mathbf{V}^{\top},Z)$*.*

Remark. The proof of 1 can be found in [39]. The proof of 2 is almost the same as in the Riemannian case.

Next, we use the above lemma joint the fact that $H_v^2=\varepsilon\bar{\mathsf{g}}(\mathbf{H},\mathbf{H})$ to obtain

$$\begin{aligned}\left\{\frac{\partial}{\partial v}\left[\left(H_v^2+\mathsf{R}_v\right)dA_v\right]\right\}_{v=0}&=\left[\varepsilon\bar{\mathsf{g}}(\triangle\mathbf{V}^{\perp},\mathbf{H})+\mathbf{V}^{\top}(H^2)+\left(\tfrac{\partial\mathsf{R}_v}{\partial v}\right)_{v=0}\right]dA\\ +\bar{\mathsf{g}}\left(\varepsilon\tilde{A}(\mathbf{H})+\mathrm{Ric}(N_\phi,N_\phi)\mathbf{H}-2(H^2+\mathsf{R})\mathbf{H},\mathbf{V}^{\perp}\right)&dA+(H^2+\mathsf{R})\,d\theta.\end{aligned}$$

On the other hand, $(H^2+\mathsf{R})\,d\theta=d\left((H^2+\mathsf{R})\,\theta\right)-\left(\mathbf{V}^{\top}(H^2+\mathsf{R})\right)dA$. Since θ vanishes on $\partial\mathsf{M}$, we have

$$\int_{\mathsf{M}}(H^2+\mathsf{R})\,d\theta=-\int_{\mathsf{M}}\left(\mathbf{V}^{\top}(H^2+\mathsf{R})\right)dA.$$

It is easy to see that Proposition 1.2. in [39] remains true in a semi-Riemannian setting. Then, we make use of it to have

$$\begin{aligned}\left\{\frac{\partial}{\partial v}\int_{\mathsf{M}_v}\left(H_v^2+\mathsf{R}_v\right)dA_v\right\}_{v=0}&=\int_{\mathsf{M}}\left[\bar{\mathsf{g}}(\mathfrak{R}(\mathbf{H}),\mathbf{V}^{\perp})+\mathbf{V}^{\perp}(\mathsf{R}^{\mathbf{V}})\right]dA\\&+\ \varepsilon\int_{\partial\mathsf{M}}\bar{\mathsf{g}}(\mathbf{H},D_\nu\mathbf{V}^{\perp})ds,\end{aligned}$$

where $\mathfrak{R}=\varepsilon(\triangle+\tilde{A})+\left(\mathrm{Ric}(N_\phi,N_\phi)-2(H^2+\mathsf{R})\right)\mathbf{I}$ is a kind of Schrödinger operator, $\mathbf{I}$ is the identity map and $\mathsf{R}^{\mathbf{V}}(\Phi(m,v))=\mathsf{R}_v(m)$. Finally, we combine this formula with (8) to get

$$\delta\mathfrak{W}(\phi)[\mathbf{V}]=\int_{\mathsf{M}}\left[\bar{\mathsf{g}}(\mathfrak{R}(\mathbf{H})+(\nabla\mathsf{R}^{\mathbf{V}})^{\perp},\mathbf{V}^{\perp})\right]dA+\int_{\partial\mathsf{M}}\bar{\mathsf{g}}(\varepsilon\mathbf{H}-\eta^{\perp},D_\nu\mathbf{V}^{\perp})ds,$$

where $(\nabla\mathsf{R}^{\mathbf{V}})^{\perp}=\varepsilon N_\phi(\mathsf{R}^{\mathbf{V}})N_\phi$ is the normal component of the gradient of $\mathsf{R}^{\mathbf{V}}$.

These computations can be summarized in the following result which gives the first variation of the Willmore functional in a semi-Riemannian manifold, $(\bar{\mathsf{M}},[\bar{\mathsf{g}}])$

Theorem 6.1 *In the previous setting,* (M,ϕ) *is a Willmore surface in* $(\bar{\mathsf{M}},[\bar{\mathsf{g}}])$ *with boundary date* $\phi(M)$*, if and only if*

$$\int_{\mathsf{M}} \left[\bar{\mathsf{g}}(\mathfrak{R}(\mathbf{H})+\varepsilon N_\phi(\mathsf{R}^{\mathbf{V}})N_\phi,\mathbf{V}^\perp)\right] dA + \int_{\partial\mathsf{M}} \bar{\mathsf{g}}(\varepsilon\mathbf{H}-\eta^\perp, D_\nu\mathbf{V}^\perp)ds = 0,$$

for any $\mathbf{V}\in\mathsf{T}_\phi\left(\mathbf{I}_{\phi(\partial\mathsf{M})}(\mathsf{M},\bar{\mathsf{M}})\right)$.

From now on, we assume the boundary conditions we are considering along this paper. Namely, let $\Gamma=\{\gamma_1,\gamma_2,\dots,\gamma_n\}$ be a finite set of non-null regular curves in $\bar{\mathsf{M}}$ with $\gamma_i\bigcap\gamma_j=\emptyset$, if $i\neq j$ and choose N_o to be a unitary vector field along Γ which is orthogonal to Γ and has constant causal character, ε, on the whole Γ. Then, we consider the space of immersions, $\mathbf{I}^\varepsilon_\Gamma(\mathsf{M},\bar{\mathsf{M}})$, made up of those immersions, $\phi:\mathsf{M}\longrightarrow\bar{\mathsf{M}}$ satisfying

$$\phi(\partial\mathsf{M})=\Gamma, \quad N_\phi=N_o \text{ along } \partial\mathsf{M} \quad \text{and} \quad \bar{\mathsf{g}}(N_\phi,N_\phi)=\varepsilon.$$

In this case (see the above remark), $D_\nu(\mathbf{V})^\perp=0$ and therefore, the boundary term vanishes. Consequently, the Willmore surfaces with prescribed Gauss map along the common boundary in $(\bar{\mathsf{M}},[\bar{\mathsf{g}}])$ are characterized by the equation

$$\int_{\mathsf{M}} \left[\bar{\mathsf{g}}(\mathfrak{R}(\mathbf{H})+\varepsilon N_\phi(\mathsf{R}^{\mathbf{V}})N_\phi,\mathbf{V}^\perp)\right] dA = 0, \quad \forall\,\mathbf{V}\in\mathsf{T}_\phi\left(\mathbf{I}^\varepsilon_\Gamma(\mathsf{M},\bar{\mathsf{M}})\right). \tag{9}$$

An easy computation shows $\triangle\mathbf{H}=(\triangle H)N_\phi$ and $\tilde{A}(\mathbf{H})=\varepsilon H\|dN_\phi\|^2N_\phi$, allowing us to reduce (9) to

$$\int_{\mathsf{M}} \left[\varepsilon\triangle H + H\left(\|dN_\phi\|^2+\mathrm{Ric}(N_\phi,N_\phi)-2(H^2+\mathsf{R})\right)+\varepsilon N_\phi(\mathsf{R}^{\mathbf{V}})\right]\bar{\mathsf{g}}(N_\phi,\mathbf{V}^\perp)dA=0, \tag{10}$$

for any $\mathbf{V}\in\mathsf{T}_\phi\left(\mathbf{I}^\varepsilon_\Gamma(\mathsf{M},\bar{\mathsf{M}})\right)$.

7 $\mathbf{A}_2$-invariant Riemannian solutions

$\mathbf{A}_2$-invariant Riemannian surfaces in $\mathbb{L}^3$ were classified in Theorem 5.4. Each surface of this type is generated by a curve, α, immersed in either $\tilde{\mathcal{R}}^+$ or $\tilde{\mathcal{R}}^-$. This curve evolves according to the motions of $\mathbf{A}_2$ to produce the symmetric surface

$$\Sigma_\alpha=\{\xi_t(\alpha(s))\,:\,s\in I,\,t\in\mathbb{R}\},$$

lying in either $\mathcal{R}^+$ or $\mathcal{R}^-$ respectively.

At this time, our aim consists of finding which curves generate surfaces Σ_α which are Riemannian solutions of the $O(2,1)$ Nonlinear Sigma Model. Since $\left(\mathbf{I}^{-1}_{\partial\Sigma_\alpha}(M,\mathbb{L}^3);\mathfrak{S}\right)$ is equivalent to $\left(\mathbf{I}^{-1}_{\partial\Sigma_\alpha}(M,\mathbb{L}^3);\mathfrak{W}\right)$, the above problem is reduced to finding which curves α generate Riemannian Willmore surfaces with prescribed time-like Gauss map along the boundary, $\partial\Sigma_\alpha$. The solution is made explicit in the following result. For a better understanding, we recall Lemma 5.1, where we showed that the Lorentz-Minkowski metric, g, on both $\mathcal{R}^+$ and $\mathcal{R}^-$ is conformal to a semi-Riemannian product of a de Sitter plane and a space-like Lorentzian circle.

Theorem 7.1 *Let α be a space-like curve immersed in either $\tilde{\mathcal{R}}^+$ or $\tilde{\mathcal{R}}^-$. Then, Σ_α is a Riemannian solution of the $O(2,1)$ Nonlinear Sigma Model, that is, a Riemannian Willmore surface with prescribed Gauss map along the common boundary in $(\mathbb{L}^3, g)$, if and only if α is a free elastica in the de Sitter plane $\left(\tilde{\mathcal{R}}^+, \frac{1}{f_+^2}g\right)$ or in the de Sitter plane $\left(\tilde{\mathcal{R}}^-, \frac{1}{f_-^2}g\right)$, respectively.*

Proof: We consider the case where α is immersed in $\tilde{\mathcal{R}}^+$, since the other case is analogous. The proof is obtained from a chain of three steps.

Step 1: We make use of the conformal invariance of the Willmore functional. In this setting, the suitable boundary conditions for the problem are $\Gamma = \partial\Sigma_\alpha$ and $N_o = N_{\Sigma_\alpha}$. Even more, as Σ_α is the image of an immersion from $[a_1, a_2] \times \mathbb{R}$, we deduce that $M = [a_1, a_2] \times \mathbb{R}$. Notice that $\mathbf{I}^{-1}_{\partial\Sigma_\alpha}(M, \mathcal{R}^+)$ is an open set of $\mathbf{I}^{-1}_{\partial\Sigma_\alpha}(M, \mathbb{L}^3)$. Using this fact, as well as the conformal invariance of the Willmore functional, it is easy to see that Σ_α is a Riemannian Willmore surface with prescribed Gauss map along the common boundary in $(\mathbb{L}^3, g)$, if and only if Σ_α is a solution of $(\mathbf{I}^{-1}_{\partial\Sigma_\alpha}(M, \mathcal{R}^+); \overline{\mathfrak{W}})$, where $\overline{\mathfrak{W}}$ is the Willmore functional of $\left(\mathcal{R}^+, \frac{1}{f_+^2}g\right)$.

From now on, we denote with a bar all the elements in $\left(\mathcal{R}^+, \frac{1}{f_+^2}g\right)$. Also, to simplify the notation, we put $\bar{N}_\alpha = \bar{N}_{\Sigma_\alpha}$ and $\bar{H}_\alpha = \bar{H}_{\Sigma_\alpha}$. Denote by $\bar{\mathsf{R}}_\alpha$ the sectional curvature of $\left(\mathcal{R}^+, \frac{1}{f_+^2}g\right)$ along Σ_α and by $\bar{K}_\alpha$ the Gaussian curvature of Σ_α with the induced metric from $\left(\mathcal{R}^+, \frac{1}{f_+^2}g\right)$.

Step 2: We compute the term $\bar{N}_\alpha(\bar{\mathsf{R}}^{\mathbf{V}})$. The surface Σ_α is a critical point of the problem $(\mathbf{I}^{-1}_{\partial\Sigma_\alpha}(M, \mathcal{R}^+)); \overline{\mathfrak{W}})$ if and only if, (10) holds on every non-null polygon contained in Σ_α, for $\varepsilon = -1$. However, it will be interesting to obtain a characterization of the critical points of $(\mathbf{I}^{-1}_{\partial\Sigma_\alpha}(M, \mathcal{R}^+); \overline{\mathfrak{W}})$ as the solution of an equation involving terms that depend only on Σ_α. In this sense, one needs to manipulate the term $\bar{N}_\alpha(\bar{\mathsf{R}}^{\mathbf{V}})$ because, a priori, it is the only one that depends on $\mathbf{V}$. Pick a point $p \in \Sigma_\alpha$, and compute $\bar{\mathsf{R}}^{\mathbf{V}}$ along a curve, γ, with $\gamma(0) = p$ and $\gamma'(0) = \bar{N}_\alpha(p)$. Let $\phi_\alpha : I \times \mathbb{R} \longrightarrow \left(\mathcal{R}^+, \frac{1}{f_+^2}g\right)$ be the parametrization of Σ_α defined as $\phi_\alpha(s,t) = \xi_t(\alpha(s))$. Write $\alpha(s) = (\alpha_1(s), 0, \alpha_3(s))$ so that $\frac{1}{f_+^2}g(\alpha', \alpha') = 1$, then a unitary normal vector to Σ_α can be computed to be

$$\bar{N}_\alpha(\phi_\alpha(s,t)) = \bar{N}_\alpha(s,t) = \xi_t((\alpha_3'(s), 0, \alpha_1'(s)) = (\alpha_3'(s), \alpha_1'(s)\sinh t, \alpha_1'(s)\cosh t).$$

Given $\mathbf{V} \in \mathsf{T}_{\phi_\alpha}\left(\mathbf{I}^{-1}_{\partial\Sigma_\alpha}(M, \mathcal{R}^+))\right)$ with compact support (remember we are working with non null polygons in Σ_α), an associated variation of ϕ_α is just

$$\Phi : (-\delta, \delta) \times I \times \mathbb{R} \longrightarrow \left(\mathcal{R}^+, \frac{1}{f_+^2}g\right), \quad \Phi(v,s,t) = \phi_\alpha(s,t) + v\mathbf{V}(\phi_\alpha(s,t)).$$

Without loss of generality, we can assume $\mathbf{V}^\top = 0$. In this case, there exists a function $f : I \times \mathbb{R} \longrightarrow \mathbb{R}$ with compact support, such that $\mathbf{V} = f\bar{N}_\alpha$, and so $\Phi(v,s,t) =$

$\phi_\alpha(s,t)+vf(s,t)\bar{N}_\alpha(s,t)$. Given a point $\Phi(v_o,s_o,t_o)$, then $\bar{\mathsf{R}}^{\mathbf{V}}(\Phi(v_o,s_o,t_o))$ is the sectional curvature of the plane generated by $\{(\partial_s\Phi)(v_o,s_o,t_o),(\partial_t\Phi)(v_o,s_o,t_o)\}$. Recall that $\left(\mathcal{R}^+,\frac{1}{f_+^2}g\right)=\left(\tilde{\mathcal{R}}^+,\frac{1}{f_+^2}g\right)\times(\mathrm{H}^+,dt^2)$ and denote by $\Pi^1:\left(\mathcal{R}^+,\frac{1}{f_+^2}g\right)\longrightarrow\left(\tilde{\mathcal{R}}^+,\frac{1}{f_+^2}g\right)$ and $\Pi^2:\left(\mathcal{R}^+,\frac{1}{f_+^2}g\right)\longrightarrow(\mathrm{H}^+,dt^2)$ the canonical projections. It is clear that $\bar{\mathcal{R}}(\Phi_s,\Phi_t,\Phi_t,\Phi_s)=\tilde{\mathcal{R}}(E_s,E_t,E_t,E_s)$, where $\bar{\mathcal{R}}$ is the curvature tensor of $\left(\mathcal{R}^+,\frac{1}{f_+^2}g\right)$ and $\tilde{\mathcal{R}}$ stands for the curvature tensor of $\left(\tilde{\mathcal{R}}^+,\frac{1}{f_+^2}g\right)$, $E_s=d\Pi^1(\partial_s\Phi)$ and $E_t=d\Pi^1(\partial_t\Phi)$. Therefore,

$$\bar{\mathsf{R}}^{\mathbf{V}}(\Phi(v_o,s_o,t_o))=\frac{\tilde{\mathcal{R}}(E_s,E_t,E_t,E_s)}{\frac{1}{f_+^2}g(\partial_s\Phi,\partial_s\Phi)\frac{1}{f_+^2}g(\partial_t\Phi,\partial_t\Phi)-(\frac{1}{f_+^2}g(\partial_s\Phi,\partial_t\Phi))^2}.$$

Observe that the normal vector at $\phi_\alpha(s_o,t_o)$ is $\bar{N}_\alpha(s_o,t_o)=\gamma'(0)$, where

$$\gamma(\tau)=\phi_\alpha(s_o,t_o)+\tau\bar{N}_\alpha(s_o,t_o)=\Phi\left(\frac{\tau}{f(s_o,t_o)},s_o,t_o\right).$$

To compute the value of $\bar{\mathsf{R}}^{\mathbf{V}}$ along γ, we have

$$\tilde{\mathcal{R}}(E_s,E_t,E_t,E_s)=\tau^2(\frac{\partial_t f}{f})^2[\tilde{\mathcal{R}}(U_o,V_1,V_1,U_o)+2\tau\tilde{\mathcal{R}}(U_o,V_1,V_1,U_1)+\tau^2\tilde{\mathcal{R}}(U_1,V_1,V_1,U_1)],$$

being $U_o=(\alpha_1',0,\alpha_3')$, $U_1=(\frac{\partial_s f}{f}\alpha_3'+\alpha_3'',0,\frac{\partial_s f}{f}\alpha_1'+\alpha_1'')$ and $V_1=(\alpha_3',0,\alpha_1')$. Also

$$\frac{1}{f_+^2}g(\partial_s\Phi,\partial_s\Phi)\frac{1}{f_+^2}g(\partial_t\Phi,\partial_t\Phi)-\left(\frac{1}{f_+^2}g(\partial_s\Phi,\partial_t\Phi)\right)^2=\frac{\alpha_3^4+b_1\tau+b_2\tau^2+b_3\tau^3+b_4\tau^4}{(\alpha_3+\tau\alpha_1')^4},$$

where b_1, b_2, b_3 and b_4 are functions that do not depend on τ. Then,

$$\bar{\mathsf{R}}^{\mathbf{V}}(\Phi(\frac{\tau}{f(s_o,t_o)},s_o,t_o))=$$

$$=\tau^2\left(\frac{\partial_t f}{f}\right)^2\frac{(\alpha_3+\tau\alpha_1')^4\left[\tilde{\mathcal{R}}(U_o,V_1,V_1,U_o)+2\tau\tilde{\mathcal{R}}(U_o,V_1,V_1,U_1)+\tau^2\tilde{\mathcal{R}}(U_1,V_1,V_1,U_1)\right]}{\alpha_3^4+b_1\tau+b_2\tau^2+b_3\tau^3+b_4\tau^4}.$$

Since $\alpha_3>0$, we obtain

$$\bar{N}_\alpha(\bar{\mathsf{R}}^{\mathbf{V}})(\phi(s_o,t_o))=\frac{d}{d\tau}_{|\tau=0}\left(\bar{\mathsf{R}}^{\mathbf{V}}\left(\Phi\left(\frac{\tau}{f(s_o,t_o)},s_o,t_o\right)\right)\right)=0.$$

Step 3: The solutions come from clamped elasticae in the de Sitter plane $\left(\tilde{\mathcal{R}}^+,\frac{1}{f_+^2}g\right)$. The computation we did in the last step allows one to characterize the solutions, Σ_α, of $(\mathbf{I}^{-1}_{\partial\Sigma_\alpha}([a_1,a_2]\times\mathrm{R},\mathcal{R}^+);\overline{\mathfrak{W}})$ as the solutions of the following Euler-Lagrange equation

$$-\triangle\bar{H}_\alpha+\bar{H}_\alpha\left(\|d\bar{N}_\alpha\|^2+\mathrm{Ric}(\bar{N}_\alpha,\bar{N}_\alpha)-2(\bar{H}_\alpha^2+\bar{\mathsf{R}}_\alpha)\right)=0\quad\text{in }\Sigma_\alpha.\tag{11}$$

Using $\|d\bar{N}_\alpha\|^2 = 4\bar{H}_\alpha^2 - 2\det(-d\bar{N}_\alpha)$ and $\bar{K}_\alpha = \bar{\mathsf{R}}_\alpha - \det(-d\bar{N}_\alpha)$, equation (11) turns out to be equivalent to

$$-\triangle \bar{H}_\alpha + \bar{H}_\alpha \left(2\bar{H}_\alpha^2 + 2\bar{K}_\alpha - 4\bar{\mathsf{R}}_\alpha + \mathrm{Ric}(\bar{N}_\alpha, \bar{N}_\alpha)\right) = 0.$$

However, $\bar{\mathsf{R}}_\alpha = 0$ because it is a mixed sectional curvature in the semi-Riemannian product, [27], namely $\left(\mathcal{R}^+, \frac{1}{f_+^2} g\right) = \left(\tilde{\mathcal{R}}^+, \frac{1}{f_+^2} g\right) \times (\mathrm{H}^+, dt^2)$. Also, $\Sigma_\alpha = \left(trace(\alpha), \frac{1}{f_+^2} g\right) \times (\mathrm{H}^+, dt^2)$ is a semi-Riemannian product and so $\bar{K}_\alpha = 0$. Recall $d\Pi^1(\partial_s\phi) = \alpha'$, $d\Pi^1(\partial_t\phi) = d\Pi^2(\bar{N}_\alpha) = 0$, and $\left(\tilde{\mathcal{R}}^+, \frac{1}{f_+^2} g\right)$ has sectional curvature 1, then we get $\mathrm{Ric}(\bar{N}_\alpha, \bar{N}_\alpha) = -1$. Bearing in mind $d\Pi^2(\partial_s\phi) = 0$, we compute the mean curvature:

$$\bar{\mathbf{H}}_\alpha = \frac{1}{2}\,(\bar{\nabla}_{\partial_s\phi}\partial_s\phi)^\perp + \frac{1}{2}\,(\bar{\nabla}_{\partial_t\phi}\partial_t\phi)^\perp = \frac{1}{2}((d\Pi^1)^{-1}(\tilde{\nabla}_{\alpha'}\alpha'))^\perp = -\frac{1}{2}\,\tilde{k}_\alpha \bar{N}_\alpha,$$

where $\bar{\nabla}$ is the Levi-Civita connection of $\left(\mathcal{R}^+, \frac{1}{f_+^2} g\right)$, $\tilde{\nabla}$ is the Levi-Civita connection of $\left(\tilde{\mathcal{R}}^+, \frac{1}{f_+^2} g\right)$ and $\tilde{k}_\alpha$ is the curvature of α in $\left(\tilde{\mathcal{R}}^+, \frac{1}{f_+^2} g\right)$. As a consequence, we obtain $\bar{H}_\alpha = -\frac{1}{2}\,\tilde{k}_\alpha$ and $\triangle\bar{H}_\alpha = -\frac{1}{2}\,\tilde{k}_\alpha''$. By using all these computations, we obtain that Σ_α is a solution of $(\mathbf{I}^{-1}_{\partial\Sigma_\alpha}([a_1, a_2] \times \mathbb{R}, \mathcal{R}^+); \overline{\mathfrak{W}})$ if and only if

$$2\tilde{k}_\alpha'' - \tilde{k}_\alpha^3 + 2\tilde{k}_\alpha = 0. \tag{12}$$

Finally, we check that this equation characterizes the elasticae in $\left(\tilde{\mathcal{R}}^+, \frac{1}{f_+^2} g\right)$.

In Section 4, we computed the equation of both space-like and time-like elastic curves in $(\mathbf{AdS}_2, \frac{1}{h^2}\, g)$, see (5). Recall that in that section, the axis $\langle\vec{x}\rangle$ was time-like, $\mathcal{B} = \{\vec{x}, \vec{y}, \vec{z}\}$ was an orthonormal basis, $\mathbf{AdS_2} = \{\vec{v} \in \mathbb{L}^3 \, : \, \langle\vec{v}, \vec{y}\rangle > 0, \, \langle\vec{v}, \vec{z}\rangle = 0\}$ and $h(p) = \langle\vec{p}, \vec{y}\rangle$, being $\vec{p}$ the position vector of the point p. Now, notice that $\left(\tilde{\mathcal{R}}^+, \hat{g} = -\frac{1}{f_+^2} g\right)$ is an anti de Sitter space, and, with this new metric, $\langle\vec{x}\rangle$ is also a time-like axis. So, a time-like curve in $\left(\tilde{\mathcal{R}}^+, \hat{g}\right)$ is an elastica if and only if $2\hat{k}'' - \hat{k}^3 + 2\hat{k} = 0$, where $\hat{k}$ is the geodesic curvature of the curve. Both $\hat{g}$ and $\frac{1}{f_+^2} g$ have the same Levi-Civita connection. Thus, by comparing the Frenet equations, it is easy to see that $\hat{k} = -\tilde{k}$, where $\tilde{k}$ is the geodesic curvature in $\left(\tilde{\mathcal{R}}^+, \frac{1}{f_+^2} g\right)$. And so, a space-like curve is a critical point of $\int_\alpha \tilde{k}^2$ in $\left(\tilde{\mathcal{R}}^+, \frac{1}{f_+^2} g\right)$, if and only if

$$2\tilde{k}'' - \tilde{k}^3 + 2\tilde{k} = 0.$$

This ends the proof of the theorem. $\square$

Remark. The solutions of (12) are

$$\bar{\kappa}_\alpha(s) = C\,\mathbf{cn}\left(\sqrt{1 - \frac{C^2}{2}}\,(s - a_o), \tilde{C}\right),$$

where $C \in \mathbb{R} \setminus \{-\sqrt{2}, \sqrt{2}\}$ and $a_o \in \mathbb{R}$ are arbitrary constants and $\tilde{C}^2 = \frac{C^2}{2C^2-4}$. If $C^2 < 2$, $s \in \mathbb{R}$; in other case, $s \in \mathbb{R} \setminus \bigcup_{n \in \mathbb{Z}} \left\{ a_o + \frac{(2n+1)\mathsf{E}'}{\sqrt{\frac{C^2}{2} - 1}} \right\}$, being E' the complete elliptic integral of first kind with modulus $\sqrt{1 - \tilde{C}^2}$.

8 $\mathbf{A}_2$-invariant Lorentzian solutions

Along this section, we describe the class of $\mathbf{A}_2$-invariant Lorentzian solutions. Firstly, we consider the case when the surfaces are contained in one fundamental region, i. e., we deal with the fundamental solutions. Certainly, this is the easy but basic case. As one can guess, two classification theorems are obtained according to the nature of the profile curve. On one hand, we obtain Lorentzian solutions, Σ_α, contained in either $\mathcal{R}^+$ or $\mathcal{R}^-$ which are generated by time-like free elasticae in the de Sitter plane. On the other hand, we also obtain a second class of Lorentzian solutions, that lie in either $\mathcal{Q}^+$ or $\mathcal{Q}^-$, coming from free elasticae in the hyperbolic plane. To be precise, we consider the following problem: Let γ be a time-like curve in either $\tilde{\mathcal{R}}^+$ or $\tilde{\mathcal{R}}^-$, or a curve in either $\tilde{\mathcal{Q}}^+$ or $\tilde{\mathcal{Q}}^-$. *What does it have to satisfy in order to make Σ_γ be a solution*? or equivalently, *What does γ have to satisfy in order to make Σ_γ be a Willmore surface with prescribed space-like Gauss map along the boundary*?

The answer to this problem is given in the next pair of statements. We omit their proofs because they are quite similar to that of Theorem 7.1 with only technical changes.

Theorem 8.1 *Let α be a time-like curve immersed in either $\tilde{\mathcal{R}}^+$ or $\tilde{\mathcal{R}}^-$. Then, Σ_α is a Lorentzian solution of the $O(2,1)$ Nonlinear Sigma Model, that is, a Lorentzian Willmore surface with prescribed Gauss map along the common boundary in $(\mathbb{L}^3, g)$, if and only if, α is a free elastica in the de Sitter plane $\left(\tilde{\mathcal{R}}^+, \frac{1}{f_+^2} g\right)$ or in the de Sitter plane $\left(\tilde{\mathcal{R}}^-, \frac{1}{f_-^2} g\right)$, respectively.*

Theorem 8.2 *Let β be a curve immersed in either $\tilde{\mathcal{Q}}^+$ or $\tilde{\mathcal{Q}}^-$. Then, Σ_β is a Lorentzian solution of the $O(2,1)$ Nonlinear Sigma Model, that is, a Lorentzian Willmore surface with prescribed Gauss map along the common boundary in $(\mathbb{L}^3, g)$, if and only if, β is a free elastica in the hyperbolic plane $\left(\tilde{\mathcal{Q}}^+, \frac{1}{h_+^2} g\right)$ or in the hyperbolic plane $\left(\tilde{\mathcal{Q}}^-, \frac{1}{h_-^2} g\right)$, respectively.*

Nevertheless, it seems convenient to give the curvature functions of the above solution generatrices.

Time-like free elastic curves in $\left(\tilde{\mathcal{R}}^+, \frac{1}{f_+^2} g\right)$ and $\left(\tilde{\mathcal{R}}^-, \frac{1}{f_-^2} g\right)$ are those time-like curves with curvature

$$\tilde{\kappa}(s) = C\, \mathbf{cn}\left(i\sqrt{1 + \frac{C^2}{2}}\,(s - a_o), \tilde{C} \right), \quad \text{for } s \in \mathbb{R} \setminus \bigcup_{n \in \mathbb{Z}} \left\{ a_o + \frac{(2n+1)}{\sqrt{1 + \frac{C^2}{2}}} \mathsf{E}' \right\}, \tag{13}$$

where $C \in \mathbb{R}$, $a_o \in \mathbb{R}$ are arbitrary constants, $\tilde{C}^2 = \frac{C^2}{2C^2+4}$ and E' is the complete elliptic integral of first kind with modulus $\sqrt{1-\tilde{C}^2}$.

Free elastic curves in $\left(\tilde{\mathfrak{Q}}^+, \frac{1}{h_+^2} g\right)$ **and** $\left(\tilde{\mathfrak{Q}}^-, \frac{1}{h_-^2} g\right)$ are those curves with curvature

$$\tilde{\kappa}_\gamma(s) = C \,\mathbf{cn}\left(\sqrt{\frac{C^2}{2} - 1}\,(s - a_o), \tilde{C}\right), \tag{14}$$

$$\text{for } \ s \in \left\{ \begin{array}{lcc} \mathbb{R} \setminus \bigcup_{n\in\mathbb{Z}} \left\{ a_o + \dfrac{2n+1}{\sqrt{1-\frac{C^2}{2}}} \mathsf{E}' \right\} & \text{if} & C^2 < 2 \\ & & \\ \mathbb{R} & \text{if} & C^2 > 2 \end{array} \right\},$$

where $C \in \mathbb{R} \setminus \{\sqrt{2}, \sqrt{2}\}$ and $a_o \in \mathbb{R}$ are arbitrary constants, $\tilde{C}^2 = \frac{C^2}{2C^2-4}$ and E' is the complete elliptic integral of first kind with modulus $\sqrt{1-\tilde{C}^2}$.

Moreover, we already know the existence of a wide family of $\mathbf{A}_2$-invariant Lorentzian surfaces which are not contained in a unique fundamental region. In other words, they are obtained by pasting fundamental rotational surfaces. Then, we investigate the existence of $\mathbf{A}_2$-invariant Lorentzian solutions which can be obtained by the gluing mechanism. The following theorem provides the connection between both the variational approach and the gluing mechanism.

Theorem 8.3 *Given a surface M, let $\phi \in \mathbf{I}^1_\Gamma(M, \mathbb{L}^3)$ be a $\mathbf{A}_2$-invariant immersion whose image intersects at least two different fundamental regions. Then, (M, ϕ) is a Lorentzian solution of the $O(2,1)$ Nonlinear Sigma Model, that is, a Lorentzian Willmore surface with prescribed Gauss map along the boundary in $(\mathbb{L}^3, g)$, if and only if, $\phi(M)$ is a $\mathbf{A}_2$-invariant connected piece (with boundary) of one of the following surfaces:*

- *A Lorentzian plane orthogonal to the axis.*
- *A one-sheet hyperboloid with arbitrary radius, centered at any point $p \in \langle \vec{x} \rangle$ and with axis $p + \langle \vec{z} \rangle$ (see Subsection 5.3).*

Proof: Given a surface M, and a $\mathbf{A}_2$-invariant Lorentzian immersion $\phi \in \mathbf{I}^1_\Gamma(M, \mathbb{L}^3)$, we know $\phi(M)$ is generated by a curve β in $\mathfrak{Q}$ and a countable family of time-like curves α_i in $\mathfrak{R}$, that are in general position. It should be noticed (see Theorems 8.1 and 8.2) that ϕ is a critical point of $(\mathbf{I}^1_\Gamma(M, \mathbb{L}^3); \mathfrak{S})$, if and only if, the following five conditions hold:

1. trace$(\beta) \cap \tilde{\mathfrak{Q}}^+$ consists of free elastic curves in $\left(\tilde{\mathfrak{Q}}^+, \frac{1}{h_+^2} g\right)$,
2. trace$(\beta) \cap \tilde{\mathfrak{Q}}^-$ consists of free elastic curves in $\left(\tilde{\mathfrak{Q}}^-, \frac{1}{h_-^2} g\right)$,

3. $\operatorname{trace}(\alpha_i) \cap \tilde{\mathfrak{R}}^+$ consists of time-like free elastic curves in $\left(\tilde{\mathfrak{R}}^+, \frac{1}{f_+^2} g\right)$ $\forall$ i,
4. $\operatorname{trace}(\alpha_i) \cap \tilde{\mathfrak{R}}^-$ consists of time-like free elastic curves in $\left(\tilde{\mathfrak{R}}^-, \frac{1}{f_-^2} g\right)$ $\forall$ i, and
5. $\phi|_{\mathsf{K}}$ is a critical point of $\left(\mathbf{I}^1_{\phi(\partial\mathsf{K})}(\mathsf{K}, \mathbb{L}^3); \mathfrak{W}^{\mathsf{K}}\right)$ for any non-null polygon $\mathsf{K} \subseteq M$, such that both $\mathsf{K} \bigcap (\mathfrak{R}^+ \cup \mathfrak{R}^-)$ and $\mathsf{K} \bigcap (\mathfrak{Q}^+ \cup \mathfrak{Q}^-)$ are not empty.

The last condition holds if and only if, for any non-null polygon K, (10) is satisfied for all $\mathbf{V} \in \mathsf{T}_\phi \left(\mathbf{I}^1_\Gamma(\mathsf{K}, \mathbb{L}^3)\right)$. Notice that $N_\phi(\mathsf{R}^{\mathbf{V}}) = 0$ in this case, because $\mathbb{L}^3$ is flat. Therefore, if ϕ satisfies the first four conditions, the last one is satisfied too.

Now, we wish to control the curves α_i for each i. It is known, for each α_i, the existence of a function, $f_i :]-\varepsilon, \varepsilon[\to \mathbb{R}$, such that $\alpha_i(t) = (f_i(t), 0, t)$ is a parametrization of α_i, in a neighborhood of $\operatorname{trace}(\alpha_i) \bigcap \langle \vec{x} \rangle$. Even more, we know that $f_i'(0) = 0$ (see proof of Theorem 5.11). The curvature function of $\alpha_i :]0, \varepsilon[\longrightarrow \left(\tilde{\mathfrak{R}}^+, \frac{1}{f_+^2} g\right)$, can be computed to be

$$\kappa_i(t) := \frac{-f_i'(t) + t f_i''(t) + (f_i'(t))^3}{(1 - (f_i'(t))^2)^{3/2}}.$$

Since $f_i'(0) = 0$, we obtain that $\lim_{t \to 0} \kappa_i(t) = 0$. On the other hand, the curvature of a time-like free elastic curve in $\left(\tilde{\mathfrak{R}}^+, \frac{1}{f_+^2} g\right)$ is given by (13). If we use the properties of the elliptic cosinus of Jacobi, it is easy to check that the module of (13) is equal or greater than $|C|$. So, condition 3 holds if, and only if, α_i is a geodesic of $\left(\tilde{\mathfrak{R}}^+, \frac{1}{f_+^2} g\right)$. A similar reasoning works for $\alpha_i :]-\varepsilon, 0[\longrightarrow \left(\tilde{\mathfrak{R}}^-, \frac{1}{f_-^2} g\right)$. As a conclusion, we obtain that conditions 3 and 4 hold if and only if α_i is a geodesic in both $\left(\tilde{\mathfrak{R}}^+, \frac{1}{f_+^2} g\right)$ and $\left(\tilde{\mathfrak{R}}^-, \frac{1}{f_-^2} g\right)$ for all i.

Next, we work with β. For each piece of $\operatorname{trace}(\beta) \bigcap \tilde{\mathfrak{Q}}^+$, there exists s_o in the closure of the domain of β, such that $p = \lim_{s \to s_o} \beta(s) \in \langle \vec{x} \rangle$ and $\exists i \in \mathcal{I}$ satisfying $\alpha_i = \alpha_{s_o}$ (see Definition 5.12). Then, there exists a function f_β, defined on $]-\varepsilon, \varepsilon[$, such that $\beta(t) = (f_\beta(t), t, 0)$ provides a parametrization of β. Again, we compute the curvature function of $\beta :]0, \varepsilon[\longrightarrow \left(\tilde{\mathfrak{Q}}^+, \frac{1}{h_+^2} g\right)$, obtaining

$$\kappa(t) := \frac{f_\beta'(t) - t f_\beta''(t) + (f_\beta'(t))^3}{(1 + (f_\beta'(t))^2)^{3/2}}.$$

Bearing in mind that $f_\beta'(0) = 0$, (see the proof of Theorem 5.11), we also obtain $\lim_{t \to 0} \kappa(t) = 0$. We compare this expression with the curvature function of an elastica in $\left(\tilde{\mathfrak{Q}}^+, \frac{1}{h_+^2} g\right)$, see (14). If $C^2 < 2$, then the absolute value of the curvature is equal or greater than $|C|$; otherwise, if s denotes the arc-length parameter, $\kappa(s)$ is a periodic function that takes the value 0 at $s = a_o + (2n+1)\mathsf{E}/\sqrt{\frac{C^2}{2} - 1}$, and the value C at $s = a_o + 4n\mathsf{E}/\sqrt{\frac{C^2}{2} - 1}$, for all $n \in \mathbb{Z}$, where E is the complete elliptic integral of first kind with modulus $\tilde{C}$. Now, we combine the behavior of (14) with both $\lim_{t\to 0}\kappa(t)=0$ and $\lim_{t\to 0}\beta(t)\in\langle\vec{x}\rangle$, to conclude that condition 1 holds if, and only if, β is a geodesic in $\left(\tilde{\mathcal{Q}}^+,\frac{1}{h_+^2}g\right)$. A similar argument can be used to see that condition 2 holds if and only if β is a geodesic in $\left(\tilde{\mathcal{Q}}^-,\frac{1}{h_-^2}g\right)$.

At this point, we take advantage on the knowledge one has on the geodesics of both the hyperbolic plane and the de Sitter one. Notice that we are regarding both surfaces as half-plane Poincaré models. We recall that the geodesics of the hyperbolic plane are those curves whose trace is either a ray perpendicular to the boundary or half a circle centered at the boundary. In the de Sitter plane, the time-like geodesics are those curves whose trace is either a ray perpendicular to the boundary or half of any of the connected components of a time-like hyperbola centered at any point of the boundary. Consequently, condition 1 holds if and only if, β can be reparametrized, in $\tilde{\mathcal{Q}}^+$, as either:

- $\beta(t)=(A,t,0)$ for $t\in]0,b[\subseteq]0,+\infty[$, where $A\in\mathbb{R}$, or
- $\beta(t)=(A+\rho\cos(t),\rho\sin(t),0)$ for $t\in]0,a[\subseteq]0,\pi[$, where $A\in\mathbb{R}$ and $\rho>0$.

Certainly, the same argument can be used for condition 2, just by replacing $\tilde{\mathcal{Q}}^+$ by $\tilde{\mathcal{Q}}^-$; $]0,\infty[$ by $]-\infty,0[$ and $]0,\pi[$ by $]-\pi,0[$. Since β is $\mathcal{C}^\infty$, we conclude that β intersects $\langle\vec{x}\rangle$ at least once, even more, it is either

- a segment perpendicular to $\langle\vec{x}\rangle$, or
- a connected piece of a circle in $(\mathcal{Q},g)$ centered at any point of $\langle\vec{x}\rangle$.

As an important consequence, the cardinal of $\{\alpha_i : i\in\mathcal{I}\}$ is either 1 or 2. Based on the geodesics of the de Sitter plane, a similar reasoning can be applied to each α_i, obtaining that conditions 3 and 4 hold if and only if for each i, α_i not only intersects $\langle\vec{x}\rangle$ but also it is either:

- a connected segment in $(\mathcal{R},g)$ perpendicular to $\langle\vec{x}\rangle$, or
- a connected piece of a connected component of a time-like Lorentzian circle in $(\mathcal{R},g)$, centered at any point of $\langle\vec{x}\rangle$.

The only remaining detail consists of finding which combinations of parametrizations of β and $\{\alpha_i : i\in\mathcal{I}\}$ give rise to $\mathcal{C}^\infty$ gluing functions (recall Theorem 5.11). The proof of the following assertions are left to the reader:

1. If $\beta(t)=(A,t,0)$ for an arbitrary constant $A\in\mathbb{R}$, then the only α that gives a $\mathcal{C}^\infty$ gluing function is $\alpha(t)=(A,0,t)$. In this case, the surface generated by α and β is a $\mathbf{A}_2$-invariant connected piece of plane $\{(A,y,z)/y,z\in\mathbb{R}\}$.
2. If β is a piece of the circle in $(\mathcal{Q},g)$ with radius $\rho>0$ and center $(A,0,0)$, that contains the point $(A+\rho,0,0)$, then to obtain a $\mathcal{C}^\infty$ gluing function in that point, α must be a piece of the future-pointing connected component of the time-like Lorentzian circle with radius ρ and center $(A,0,0)$.

3. If β is a piece of the circle in $(\mathcal{Q}, g)$ with radius $\rho > 0$ and center $(A, 0, 0)$, that contains the point $(A - \rho, 0, 0)$, then, to obtain a $\mathcal{C}^\infty$ gluing function in that point, α must be a piece of the past-pointing connected component of the time-like Lorentzian circle with radius ρ and center $(A, 0, 0)$.

Finally, in the last two cases, i. e., when β is a piece of circle in $(\mathcal{Q}, g)$, the surface generated by $\{\beta\} \cup \{\alpha_i : i \in \mathcal{I}\}$ is just a $\mathbf{A}_2$-invariant connected piece of a one-sheet hyperboloid with center $p \in \langle \vec{x} \rangle$, and axis $p + \langle \overrightarrow{z} \rangle$. $\square$

9 $\mathbf{A}_3$-invariant Surfaces in $\mathbb{L}^3$

In this section, we obtain, up to similarities in the Lorentz-Minkowski space, the whole class of solutions of the $O(2, 1)$ Nonlinear Sigma Model which are symmetric under the group $\mathbf{A}_3$. As above, the first step consists of finding the symmetric points, i. e., the immersions that are $\mathbf{A}_3$-invariant. In this sense, we will consider the corresponding fundamental regions where one can get fundamental symmetric surfaces, well-known in the literature as rotational surfaces with light-like axis, see for example [19]. Then, we will pay attention to the, a priori, reasonable problem of gluing two fundamental symmetric surfaces which are contained in different fundamental regions. Nevertheless, we will see that a gluing mechanism does not work in this case, so we cannot paste two rotational surfaces with light-like axis, lying in different fundamental regions, to provide an $\mathbf{A}_3$-invariant surface.

Given $\vec{x} \in \mathbb{L}^3$ a light-like vector, we choose a basis $\mathcal{B} = \{\vec{x}, \vec{y}, \vec{z}\}$, such that: (1) $\vec{y}$ is a light-like vector with $\langle \vec{x}, \vec{y} \rangle = -1$, and (2) $\vec{z}$ is a unitary space-like vector orthogonal to the plane $\mathrm{Span}\{\vec{x}, \vec{y}\}$. From now on, we will use coordinates with respect to $\mathcal{B}$, so $g \equiv -2dx\,dy + dz^2$. In $\mathbb{L}^3 \setminus \langle \vec{x} \rangle$ we will distinguish the following *fundamental regions*:

$$\mathcal{S}^+ = \{(x, y, z) \in \mathbb{L}^3 \,:\, y > 0\}, \quad \text{and} \quad \mathcal{S}^- = \{(x, y, z) \in \mathbb{L}^3 \,:\, y < 0\}.$$

Put $\mathcal{S} = \{(x,y,z) \in \mathbb{L}^3 \,:\, z = 0\}$ and $\mathcal{T} = \{(x,y,z) \in \mathbb{L}^3 \,:\, y = 0\}$, and consider the following open half planes:

$$\begin{aligned} \tilde{\mathcal{S}}^+ &= \mathcal{S}^+ \cap \mathcal{S} = \{(x,y,0) \in \mathbb{L}^3 \,:\, y > 0\}, \text{ and} \\ \tilde{\mathcal{S}}^- &= \mathcal{S}^- \cap \mathcal{S} = \{(x,y,0) \in \mathbb{L}^3 \,:\, y < 0\}. \end{aligned}$$

We also have the following parabolas, that are orbits under the action of $\mathbf{A}_3$:

$$\begin{aligned} \mathcal{P}^+ &= \{(x,1,z) \in \mathbb{L}^3 \,:\, -2x + z^2 = 0\} = \{(t^2/2, 1, t) \in \mathbb{L}^3 \,:\, t \in \mathbb{R}\}, \text{ and} \\ \mathcal{P}^- &= \{(x,-1,z) \in \mathbb{L}^3 \,:\, 2x + z^2 = 0\} = \{(-t^2/2, -1, t) \in \mathbb{L}^3 \,:\, t \in \mathbb{R}\}. \end{aligned}$$

It should be noticed that $\mathcal{P}^+$ and $\mathcal{P}^-$ are space-like in $\mathbb{L}^3$ with metric dt^2. Next, we define positive functions

$$\begin{aligned} l_+ : \tilde{\mathcal{S}}^+ \longrightarrow \mathbb{R}, \quad l_+(x,y,0) &= y, \text{ and} \\ l_- : \tilde{\mathcal{S}}^- \longrightarrow \mathbb{R}, \quad l_-(x,y,0) &= -y. \end{aligned}$$

In this setting, it is not difficult to check the following warped product decompositions

$$\begin{aligned} (\mathcal{S}^+, g) &= (\tilde{\mathcal{S}}^+, g) \times_{l_+} (\mathcal{P}^+, dt^2), \text{ and} \\ (\mathcal{S}^-, g) &= (\tilde{\mathcal{S}}^-, g) \times_{l_-} (\mathcal{P}^-, dt^2). \end{aligned}$$

Furthermore, when we make the obvious conformal changes, it is easy to see that the surfaces $\left(\tilde{\mathcal{S}}^+, \frac{1}{l_+^2} g\right)$ and $\left(\tilde{\mathcal{S}}^-, \frac{1}{l_-^2} g\right)$ are anti de Sitter planes with curvature -1. Consequently, we obtain the following result.

Lemma 9.1 $\left(\mathcal{S}^+, \frac{1}{l_+^2} g\right)$ *and* $\left(\mathcal{S}^-, \frac{1}{l_-^2} g\right)$ *are semi-Riemannian products of an anti de Sitter plane and a space-like parabola.*

The following result classifies the $\mathbf{A}_3$-invariant surfaces. In particular, it proves that the surfaces of this class lie in one fundamental region.

Theorem 9.1 *Let M be a connected surface and $\phi : M \longrightarrow \mathbb{L}^3$ a non-degenerate immersion. Then, $(M, \phi^*(g))$ is $\mathbf{A}_3$-invariant if and only if one of the following statements hold:*

1. *If $(M, \phi^*(g))$ is Riemannian, there exists a space-like curve, α, immersed in either $\tilde{\mathcal{S}}^+$ or $\tilde{\mathcal{S}}^-$, such that $\phi(M) = \{\varsigma_t(\mathrm{trace}(\alpha))/t \in \mathbb{R}\}$.*
2. *If $(M, \phi^*(g))$ is Lorentzian, there exists a time-like curve, α, immersed in either $\tilde{\mathcal{S}}^+$ or $\tilde{\mathcal{S}}^-$, such that $\phi(M) = \{\varsigma_t(\mathrm{trace}(\alpha))/t \in \mathbb{R}\}$.*

Proof: It is clear that, given any non-null curve, α, immersed in either $\tilde{\mathcal{S}}^+$ or in $\tilde{\mathcal{S}}^-$, then, the surface parametrized by $X(s,t) = \varsigma_t(\alpha(s))$ provides an $\mathbf{A}_3$-invariant surface, [19]. If α is space-like, then the surface is Riemannian, and, if α is time-like, the surface is Lorentzian. It is also easy to see the converse, given an $\mathbf{A}_3$-invariant surface immersed in either $\mathcal{S}^+$ or $\mathcal{S}^-$, then, there exists a non-null curve, α immersed in either $\tilde{\mathcal{S}}^+$ or $\tilde{\mathcal{S}}^-$ such that the surface is parametrized as $X(s,t) = \varsigma_t(\alpha(s))$ and so it is $\mathbf{A}_3$-invariant.

Thus, we only need to check that there do not exist $\mathbf{A}_3$-invariant surfaces intersecting the plane $\mathcal{T}$. First, notice that the orbits contained in $\mathcal{T}$ are always light-like, so Riemannian $\mathbf{A}_3$-invariant surfaces intersecting the plane $\mathcal{T}$ cannot exist.

On the other hand, let us assume there exists a Lorentzian $\mathbf{A}_3$-invariant surface immersed in $\mathbb{L}^3$, $\phi(M)$, intersecting the plane $\mathcal{T}$. Then, $\phi(M) \cap \mathcal{S}^+$ and $\phi(M) \cap \mathcal{S}^-$ are the union of a countable family of $\mathbf{A}_3$-invariant surfaces generated by time-like curves in $\tilde{\mathcal{S}}^+$ and $\tilde{\mathcal{S}}^-$, respectively. Note that the boundary of each of these curves has only one point in $\langle \vec{x} \rangle$, because of its causality. Therefore, we must check that none of the following cases hold:

1. There exist two time-like curves $\alpha^+ :]0,\delta[\longrightarrow \tilde{\mathcal{S}}^+$ and $\alpha^- :]-\delta, 0[\longrightarrow \tilde{\mathcal{S}}^-$ $(\delta > 0)$ such that
   (a) $\lim_{s\to 0} \alpha^+(s) = \lim_{s\to 0} \alpha^-(s)$ is a point of $\langle \vec{x} \rangle$.
   (b) The surfaces generated by both curves can be glued, obtaining a smooth $\mathbf{A}_3$-invariant Lorentzian surface.
2. There exist two time-like curves both in either $\tilde{\mathcal{S}}^+$ or $\tilde{\mathcal{S}}^-$, satisfying (a) and (b).
3. There exists a time-like curve in either $\tilde{\mathcal{S}}^+$ or $\tilde{\mathcal{S}}^-$, that generates an $\mathbf{A}_3$-invariant surface that glue smoothly with $\langle \vec{x} \rangle$, or a part of it, and the induced metric along the union is Lorentzian.

To do so, we study the behavior of the surfaces generated by a curve immersed in $\tilde{\mathcal{S}}^+$ and a curve immersed in $\tilde{\mathcal{S}}^-$, in a neighborhood of $\langle \vec{x} \rangle$. Let $\alpha^+ :]0,\delta[\longrightarrow \tilde{\mathcal{S}}^+$ be a time-like curve such that $\lim_{s\to 0} \alpha^+(s) \in \langle \vec{x} \rangle$. We define r^+ as

$$r^+ = \{\lim_{s\to 0} \varsigma_t(\alpha^+(s))/t \in \mathbb{R}\} = \{\lim_{s\to 0} \alpha^+(s) + \lambda\vec{x}/\lambda > 0\}.$$

Let $\alpha^- :]-\delta, 0[\longrightarrow \tilde{\mathcal{S}}^-$ be a time-like curve such that $\lim_{s\to 0} \alpha^-(s) \in \langle \vec{x} \rangle$. We define r^- as

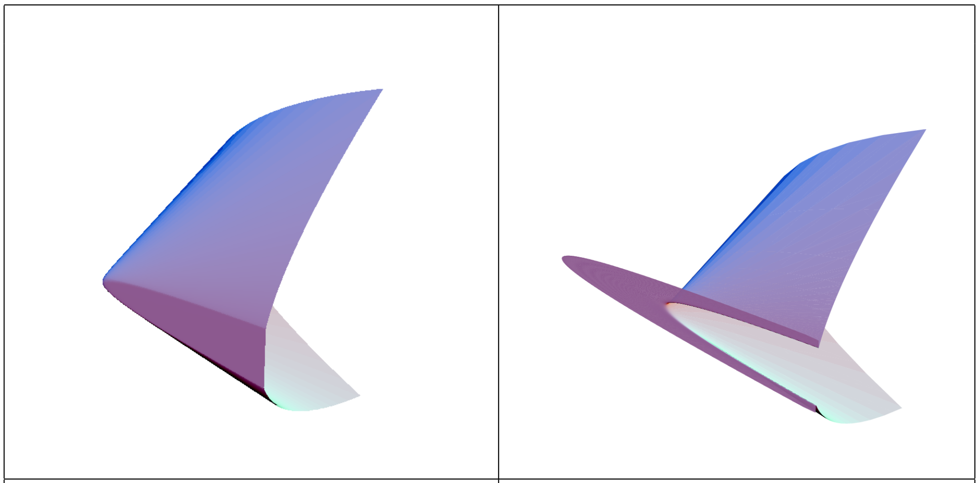
$$r^- = \{\lim_{s\to 0} \varsigma_t(\alpha^-(s))/t \in \mathbb{R}\} = \{\lim_{s\to 0} \alpha^-(s) + \lambda\vec{x}/\lambda < 0\}.$$

Then, cases 1 and 2 are not possible, because in both cases, the surfaces obtained after the gluing are not a $\mathcal{C}^\infty$ surface in a neighborhood of the point in which both curves glue. A necessary condition for case 3 to hold, is that the curve obtained by gluing α and r^+ or r^- (depending on if α is immersed in $\tilde{\mathcal{S}}^+$ or $\tilde{\mathcal{S}}^-$, respectively) must be $\mathcal{C}^\infty$. But in that case, the tangent plane of the surface along r^+ or r^- is $\{(x,0,z)/x,z \in \mathbb{R}\}$, so the induced metric is not Lorentzian along the union. $\square$

Finally, the last result classifies the $\mathbf{A}_3$-invariant surfaces which are also solutions of the $O(2,1)$ Nonlinear Sigma Model.

Theorem 9.2 *Let α be a non-null curve immersed in $\mathbb{S}$. Then, $\Sigma_\alpha = \{\varsigma_t(\text{trace}(\alpha))/t \in \mathbb{R}\}$ is a non-degenerate solution of the $O(2,1)$ Nonlinear Sigma Model, that is, a non-degenerate Willmore surface with prescribed Gauss map along the common boundary in $(\mathbb{L}^3, g)$, if and only if α is a free elastica in the anti de Sitter plane $\left(\tilde{\mathbb{S}}^+, \frac{1}{l_+^2} g\right)$ or in the anti de Sitter plane $\left(\tilde{\mathbb{S}}^-, \frac{1}{l_-^2} g\right)$, respectively.*

The proof is analogous to the one of Theorem 7.1, so it is left to the reader. We only have to recall that the curvature function for free elasticae in the de Sitter plane were made explicit at the end of Section 4, but in our case, we have to substitute ε_2 by ε.



$\mathbf{A}_3$-invariant Riemannian solution | $\mathbf{A}_3$-invariant Lorentzian solution

10 Appendix: A Gauss-Bonnet formula for non-null polygons

The Lorentzian version of the Gauss-Bonnet formula given in [8] is only true when the boundary, $\Gamma = \{\gamma_1, \gamma_2, \ldots, \gamma_n\}$, is made exclusively of time-like pieces. However, we are considering a more general setting where some pieces of the boundary might be space-like while others can be time-like. Therefore, we need to extend the Gauss-Bonnet formula to this more general context.

Let (S, g) be a Lorentzian surface. We choose an orientation joint a time-orientation in S. For any unitary vector $\vec{w} \in T_pS$, denote by $\vec{w}^\perp \in T_pS$ the unique unitary vector such that $\langle \vec{w}, \vec{w}^\perp \rangle = 0$ and the ordered basis $\{\vec{w}, \vec{w}^\perp\}$ is positively oriented. By choosing such basis and expressing vectors by their corresponding coordinates, we can define the concept of hyperbolic angle, [8], made by a pair of time-like vectors. Let $\vec{u}, \vec{v}$ be two unitary time-like vectors, if they are future-pointing (or past-pointing), the angle, $\angle[\vec{u},\vec{v}]$, from $\vec{u}$ to $\vec{v}$ is the number θ such that

$$A_\theta \cdot \vec{u} = \vec{v}, \quad \text{with} \quad A_\theta = \begin{pmatrix} \cosh\theta & \sinh\theta \\ \sinh\theta & \cosh\theta \end{pmatrix}.$$

Once we have defined the angle between two future-pointing (or past-pointing) unitary time-like vectors, we can define the angle between arbitrary unitary vectors according to the following cases: [25]:

1. If $\vec{u}$ is future-pointing and $\vec{v}$ past-pointing (or viceversa) unitary time-like vectors, define
$$\angle[\vec{u},\vec{v}] = \angle[\vec{u},-\vec{v}].$$
2. If $\vec{u}$ and $\vec{v}$ are unitary space-like vectors, then $\vec{u}^\perp$ and $\vec{v}^\perp$ are unitary time-like vectors and so, we define
$$\angle[\vec{u},\vec{v}] = \angle[\vec{u}^\perp,\vec{v}^\perp].$$
3. Finally, if $\vec{u}$ is time-like and $\vec{v}$ space-like, we define
$$\angle[\vec{u},\vec{v}] = \angle[\vec{u},\vec{v}^\perp]; \quad \angle[\vec{v},\vec{u}] = \angle[\vec{v}^\perp,\vec{u}].$$

With these definitions, Lemma 1 of [8] still holds, see [25].

The main purpose of the next step is to realize, *à la Euler*, the geodesic curvature of any non-null curve, $\delta(s)$, in S. Without loss of generality, we may assume that $\delta(s)$ is arclength parametrized, with Frenet apparatus $\{T(s) = \delta'(s), T^\perp(s)\}$, curvature function κ, and Frenet equations

$$\nabla_T T = \varepsilon_2 \kappa\, T^\perp, \quad \nabla_T T^\perp = -\varepsilon_1 \kappa\, T,$$

where ∇ stands for the Levi-Civita connection of (S, g), $\varepsilon_1 = \mathsf{g}(T,T)$ and $\varepsilon_2 = \mathsf{g}(T^\perp, T^\perp)$. On the other hand, let $Z(s)$ be a unitary time-like vector field parallel along $\delta(s)$. By choosing $Z(0)$ future-pointing, then it is so at every point because parallel displacement preserves time-orientation. Notice that $Z^\perp(s)$ is also parallel along $\delta(s)$. Now, if we denote by $\varphi(s) = \angle[T(s), Z(s)]$, the conclusion is

$$\varphi'(s) = -\kappa(s). \tag{15}$$

To check this formula, we will distinguish two cases:

1. If $\delta(s)$ is time-like, the proof can be found in [8].
2. If $\delta(s)$ is space-like, then, in the basis $\{Z(s), Z^\perp(s)\}$, we have
$$\begin{aligned} A_{-\varphi(s)} \cdot Z(s) &= \pm T^\perp(s), & (16) \\ A_{-\varphi(s)} \cdot Z^\perp(s) &= \mp T(s), & (17) \end{aligned}$$
depending on whether $T^\perp$ is future-pointing or past-pointing, respectively. Next, we differentiate (16) with respect to s, compare it with the Frenet equations and finally, combine with (17) to obtain (15).

After this point, we can follow step by step the proof of [8], valid for time-like polygons (i. e., non-null polygons with time-like boundary) to obtain the following result.

Gauss-Bonnet formula for non null polygons: Let $(S, \mathbf{g})$ be a Lorentzian surface and let $\mathsf{K} \subset S$ be a non-null polygon such that $\partial\mathsf{K}$ is a simple closed curve made up of a finite number of smooth non-null curves, $\delta_j(s)$, $1 \leq j \leq r$. Suppose that δ_j starts at $p_j \in S$ with initial unitary speed $\vec{t_j}$ and ends at $p_{j+1} \in S$ with terminal unitary speed $\vec{u}_j$, where $p_{r+1} = p_1$. Denote the exterior angles at vertices as follows: $\theta_1 = \angle[\vec{u}_1, \vec{t_2}]$, $\theta_2 = \angle[\vec{u}_2, \vec{t_3}]$,. . .,$\theta_{r-1} = \angle[\vec{u}_{r-1}, \vec{t_r}]$ and $\theta_r = \angle[\vec{u}_r, \vec{t_1}]$. In this framework, we have

$$-\int_{\mathsf{K}} K\, dA + \int_{\partial\mathsf{K}} \kappa\, ds + \sum_{j=1}^{r} \theta_j = 0,$$

where K stands for the Gaussian curvature of $(S, \mathbf{g})$ and κ denotes the geodesic curvature along $\partial\mathsf{K}$.
